<b>Abstract:</b>	<p>Date palms are highly economically important species in hot arid regions, which may suffer ozone (<math>O_3</math>) pollution equivalently to heat and water stress. However, little is known about date palm sensitivity to <math>O_3</math>. Therefore, to identify their resistance mechanisms against elevated <math>O_3</math>, physiological parameters (leaf gas exchange, chlorophyll fluorescence and leaf pigments) and biomass growth responses to realistic <math>O_3</math> exposure were tested in an isoprene-emitting date palm (<i>Phoenix dactylifera</i> L. cv. Nabut Saif) by a Free-Air Controlled Exposure (FACE) facility with three levels of <math>O_3</math> (ambient [AA, 45 ppb as 24-h average], 1.5 x AA and 2 x AA). We found a reduction of photosynthesis only at 2 x AA although some foliar traits known as early indicators of <math>O_3</math> stress responded already at 1.5 x AA, such as increased dark respiration, reduced leaf pigment content, reduced maximum quantum yield of PSII, inactivation of the oxygen evolving complex of PSII and reduced performance index PI<sub>TOT</sub>. As a result, <math>O_3</math> did not affect most of the growth parameters although significant declines of root biomass occurred only at 2 x AA, suggesting that this date palm cultivar showed an intermediate susceptibility to <math>O_3</math>. The major mechanism in date palm for reducing the severity of <math>O_3</math> impacts was a restriction of stomatal <math>O_3</math> uptake due to low stomatal conductance and <math>O_3</math>-induced stomatal closure. In addition, an increased respiration in elevated <math>O_3</math> may indicate a raised capacity of catabolizing metabolites for detoxification and repair. Interestingly, date palm produced low amounts of monoterpenes, whose emission was stimulated in 2 x AA, although isoprene emission declined at both 1.5 and 2 x AA. Our results warrant more research on a biological significance of terpenoids in plant resistance against <math>O_3</math> stress.</p>

## Abstract

Date palms are highly economically important species in hot arid regions, which may suffer ozone (O<sub>3</sub>) pollution equivalently to heat and water stress. However, little is known about date palm sensitivity to O<sub>3</sub>.

26 Therefore, to identify their resistance mechanisms against elevated O<sub>3</sub>, physiological parameters (leaf gas  
1  
27 exchange, chlorophyll fluorescence and leaf pigments) and biomass growth responses to realistic O<sub>3</sub>  
2  
3  
4  
5  
28 exposure were tested in an isoprene-emitting date palm (*Phoenix dactylifera* L. cv. Nabut Saif) by a Free-Air  
6  
7  
29 Controlled Exposure (FACE) facility with three levels of O<sub>3</sub> (ambient [AA, 45 ppb as 24-h average], 1.5 x AA  
8  
9  
30 and 2 x AA). We found a reduction of photosynthesis only at 2 x AA although some foliar traits known as  
10  
11  
31 early indicators of O<sub>3</sub> stress responded already at 1.5 x AA, such as increased dark respiration, reduced leaf  
12  
13  
32 pigment content, reduced maximum quantum yield of PSII, inactivation of the oxygen evolving complex of  
14  
15  
33 PSII and reduced performance index PI<sub>TOT</sub>. As a result, O<sub>3</sub> did not affect most of the growth parameters  
16  
17  
34 although significant declines of root biomass occurred only at 2 x AA, suggesting that this date palm cultivar

Surface ozone (O<sub>3</sub>) is a secondary pollutant formed via reactions from precursors, e.g. nitrogen oxides, carbon monoxide, methane and volatile organic compounds (VOC) in the presence of sunlight. It is an ubiquitous air pollutant, which at present reaches potentially phytotoxic levels in many regions of the world (Mills et al., 2018). Ozone impacts on vegetation have been largely investigated (Paoletti, 2007; Li et al., 2017; Grulke and Heath, 2020), but there is still a lack of knowledge on species from under-investigated areas of the world, e.g. on palms.

Palms are perennial flowering plants in the monocot order Arecales, mostly restricted to tropical and subtropical climates. Among the > 2600 species of palm, only date palm (*Phoenix dactylifera* L.) has been investigated for O<sub>3</sub> responses so far and showed relatively high sensitivity following short-term exposure (8 h) to a spike of O<sub>3</sub> (200 ppb) (Du et al., 2018). Date palm is appreciated both as ornamental tree and as food source, and is widely cultivated wherever the temperature is optimal for ripening of its edible sweet fruits (ab. 40 °C), especially in Northern Africa, the Middle East and South Asia. In these areas, high temperature, intense solar radiation and clear sky favour O<sub>3</sub> formation (Smoydzin et al., 2012; Radaideh, 2016). In fact, elevated O<sub>3</sub> precursor emissions and high O<sub>3</sub> pollution have been documented over the Middle East (Smoydzin et al., 2012) and South Asia (Fry et al., 2012), because of urban development and industrialization (Ohara et al., 2007; Radaideh, 2016) as well as long-range transport of precursors (Lelieveld et al., 2009; Kulshrestha and Kumar, 2014). Although date palm requires good soil water availability for optimal growth, it can tolerate drought (Arab et al., 2016). It presents thick leaves (Doaygei et al., 2013) and low gas exchanges (Arab et al., 2016) that are considered xeromorphic adaptations able to induce cross-tolerance to O<sub>3</sub> (Paoletti, 2006). Date palm sensitivity to O<sub>3</sub> is thus worth of further investigations.

78 Ozone may reduce plant growth. According to a meta-analysis by Li et al. (2017), an experimentally  
1  
279 enhanced O<sub>3</sub> exposure (mean concentrations = 116 ppb) reduced 14% of total biomass compared with the  
3  
4  
580 control (mean concentrations = 21 ppb). The negative effect was highlighted in below-ground rather than  
6  
781 above-ground growth (Agathokleous et al., 2016). A reduction in plant growth by O<sub>3</sub> is generally related to a  
8  
982 damage to photosynthetic systems in leaves (Hoshika et al., 2020a, b). Ozone-induced negative effects on  
10  
11  
1283 photosynthesis may be associated with a reduced performance of chlorophyll fluorescence and a decline of  
13  
1484 photosynthetic pigments (Li et al., 2017; Cotrozzi et al., 2018a).

15  
1685  
17  
18  
1986 Elevated O<sub>3</sub> exposure also impacts on isoprene emission from leaves. In addition to the pivotal role of VOC  
20  
2187 on O<sub>3</sub> formation in the atmosphere, biogenic isoprene biosynthesis and emission is postulated to contribute  
22  
2388 to scavenge O<sub>3</sub>-induced reactive oxygen species (ROS) (Loreto and Velikova, 2001; Vickers et al., 2009),  
24  
25  
2689 maintaining photochemical efficiency and photosynthetic stability (Pollastri et al., 2019) and acting as a  
27  
2890 signal molecule to alter gene expression for abiotic stress (Harvey and Sharkey, 2016; Zuo et al., 2019).  
29  
30  
3191 Palms usually emit isoprene from the leaves. For example, Parra (2008) and Hewitt et al. (2009) evaluated  
32  
3392 the contribution of the high-isoprene-emitting oil palm in tropical plantations to the production of surface  
34  
3593 O<sub>3</sub> pollution. Arab et al. (2016) found that heat but not drought stimulated the biosynthesis of isoprene in  
36  
37  
3894 date palm, with photosynthesis only weakly affected by both stressors.  
39

4095  
41  
4296 The aim of this study was to clarify the mechanisms of date palm sensitivity to O<sub>3</sub> exposure under realistic  
43  
44  
4597 ambient conditions in a last-generation O<sub>3</sub> Free-Air Controlled Exposure (O<sub>3</sub> FACE) experiment. The  
46  
4798 questions addressed here are: (i) does O<sub>3</sub> affect the response of biomass and leaf gas exchange  
48  
4999 (photosynthetic parameters and VOC emission) in date palm? (ii) is date palm sensitivity explained by  
50  
51  
52100 avoidance of O<sub>3</sub> stress (restriction of O<sub>3</sub> uptake due to stomatal closure)? (ii) is date palm sensitivity  
53  
54101 affected by isoprene emission from leaves?  
55

**Experimental design and conditions**

The experiment was carried out from May 20<sup>th</sup> to August 20<sup>th</sup>, 2019, in a free-air controlled exposure (FACE) facility located in Mediterranean Italy (43°48'59" N, 11°12'01" E, 55 m a.s.l.), where ambient summer conditions allow the growth of tropical plant species (Moura et al., 2018; Fernandes et al., 2019). Three levels of O<sub>3</sub> were applied: ambient (AA), 1.5 times ambient (1.5 x) and twice ambient O<sub>3</sub> concentrations (2 x), with three replicated plots per each O<sub>3</sub> level. A detailed description of the ozone FACE facility is in Paoletti et al. (2017).

Environmental conditions were continuously monitored by recording hourly values of soil moisture by ECH2O EC-5 sensors (Decagon Devices, Pullman WA, USA) and of air temperature, photosynthetic active radiation, relative humidity of the air and precipitation by a Watchdog station (Mod. 2000; Spectrum Technology, Inc., Aurora, IL, USA). Fig. 1 shows environmental conditions (Fig. 1a) and O<sub>3</sub> levels (Fig. 1b) during the experiment. AOT40 (Accumulated dose of ozone Over a Threshold of 40 ppb) values at the end of the 92 days of the experiment were 20,071 ppb·h in AA, 46,297 ppb·h in 1.5 x AA and 61,959 ppb·h in 2 x AA. POD1 (Phytotoxic Ozone Dose above a threshold of 1 nmol m<sup>-2</sup> s<sup>-1</sup>) values were 2.43 mmol m<sup>-2</sup> in AA, 3.93 mmol m<sup>-2</sup> in 1.5 x AA and 4.64 mmol m<sup>-2</sup> in 2 x AA. The details of POD1 calculation are described in Suppl. Fig. S1 and Table S1.

Forty-five micro-propagated 1-year-old plants of date palm (ab. 1 m high) of the cultivar Nabut Saif, raised in a soil-less peat-based potting mix in a plastic "torpedo" pot, were transferred into 4.5 l pots filled with 70% gravel (diameter 3-6 mm) and 30% commercial planting peat-rich soil in December 2018. Pots were kept to overwinter in a phytotron on plastic tablets continuously filled with tap water at 1-2 cm height and watered daily with 50 ml tap water per pot. Conditions included artificial illumination at ca. 200 μmol m<sup>-2</sup> s<sup>-1</sup>, 25°C temperature, with a 16/8h light/dark cycle. Plants were transferred to 20 l pots and to shaded

130 tunnels in the open on 1<sup>st</sup> May, 2019, and moved to full light after one week. Each pot was fertilized once a  
1  
131 month with NPK 20:10:20 with micronutrients (Soluplant 20.10.20, Haifa, Israel). Five potted plants were  
3  
132 placed in each plot, for a total of 45 plants. Each pot was watered daily by a drip irrigation system with 800  
5  
6  
133 ml of tap water, i.e. 90% of field capacity.

65

On 20<sup>th</sup> August, Chl *a* fluorescence was measured on attached leaves dark adapted with Hansatech leaf clips (30 min) (from all the 5 plants per plot) with three leaves per plant, by a Plant Efficiency Analyser

156 (Pocket PEA fluorimeter, Hansatech Instruments Ltd., King's Lynn, UK). The emitter wavelength of a non-  
1  
157 modulated light source was 625 nm for the actinic light LED. High quality optical band pass filters were used  
3  
158 for the detector (Chl *a* fluorescence 730±15 nm). Measurements were performed on circular areas of the  
5  
159 leaves of 2 mm diameter, using Hansatech leaf clips homogeneously illuminated by actinic light LEDs set to  
8  
160 a saturating light intensity of 3500  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ . Chl *a* fluorescence was recorded within five time  
10  
161 intervals; every 10  $\mu\text{s}$  for the initial fluorescence (0 - 300  $\mu\text{s}$ ), every 100  $\mu\text{s}$  (0.3 - 3 ms), 1 ms (3 - 30 ms), 10  
12  
162 ms (0.03 - 0.3 s), 100 ms (0.3 - 1 s). Raw data were transferred and processed using PEA Plus software  
15  
163 (Hansatech Instruments Ltd.). The primary photochemistry of PSII was further evaluated using well  
17  
164 established parameters described in Suppl. Table S2, Suppl. Fig. S2 and Suppl. Fig. S3a-c, according to  
20  
165 formulations previously published (Papageorgiou and Govindjee, 2004; Strasser et al., 2010; Bussotti et al.,  
22  
166 2011; Chen et al., 2016). The changes in these parameters are associated with various stressors as well as  
24  
167 overall plant vitality (Kalaji et al., 2017). All parameters were optimized for a high throughput workflow of  
27  
168 Chl *a* fluorescence raw data using the open source software "Libre Office 6" (The Document Foundation,  
29  
169 Berlin, Germany). The data were plotted graphically and statistically analyzed by using "Prism 8.4 for Mac  
31  
170 OS-X" software (GraphPad Software Inc., La Jolla, USA).

### 171 172 ***Measurement of synthesis and emission of volatile organic compounds***

173  
174 On August 1<sup>st</sup>-2<sup>nd</sup>, from 10 to 12 CET, one leaf (2<sup>nd</sup> fully expanded leaves) from two plants per replicated  
43  
175 plot was sampled for emission of VOC following the methodology by Yuan et al. (2016). In detail, the  
46  
176 central part of the leaf was included into the 6 cm<sup>2</sup> cuvette of a LI-6400 system (Li-Cor 6400 instruments,  
48  
177 Lincoln, NE, USA). Measurements were performed at standard conditions of 30°C and 1000  $\mu\text{mol m}^{-2} \text{s}^{-1}$   
50  
178 PPF. When photosynthesis reached a steady state, 2-l air samples were collected through a purified  
53  
179 Tenax-TA glass tube (Thermal Desorption Tubes, filled with 100 mg Tenax-TA adsorbent (Mesh 60/80),  
55  
180 Gerstel, Germany) with a vacuum sampler pump (VSS-1, AP Buck, USA). Blank (no leaf) samples were  
58  
181 collected at the beginning and end of each day of sampling. The traps were sealed with Teflon-coated brass  
60  
61  
62  
63  
64  
65

182 caps immediately after collection and stored at -20°C until analysis to avoid any chemical alteration and/or  
1  
183 artefacts. Then, the samples were processed and analyzed with a thermal-desorber (Markes International,  
3  
184 Series 2 Unity) connected to a 7890 A gas chromatograph coupled with a 5975C mass detector (GC-MS,  
5  
6  
185 Agilent Technologies, Wilmington, USA) as described in Baraldi et al. (2019). Identification and  
8  
186 quantification of the sampled isoprenoids were carried out according to Rapparini et al. (2004).  
10

11  
187  
12  
13  
188 All pinnae of the 2<sup>nd</sup> fully expanded leaf of each plant were cut into small pieces, shock frozen in liquid  
15  
189 nitrogen and ground to fine powder. RNA was isolated using the NucleoSpin RNA Plant Kit (Macherey-  
17  
190 Nagel) according to the manufacturers advice with the following exceptions. Leaf tissues were frozen in  
20  
191 liquid nitrogen and ground to powder. For each sample, 50 mg of leaf tissue powder were first mixed with  
22  
192 500 µl Fruit-mate™ (Taraka Bio Inc.) and centrifuged for 5 min at 4 °C and 12000 g to remove  
24  
25  
193 polysaccharides and polyphenols. The supernatant was mixed with 500 µl RA1 buffer (containing 1:1000  
27  
194 TCEP) from the NucleoSpin RNA Plant Kit. The mixture was transferred to the filter columns in two steps  
29  
195 and the filtrate was collected in a new collection tube and mixed well with the same volume of 70%  
31  
32  
196 ethanol. The mixture was added again in two steps to the NucleoSpin RNA plant Colum and centrifuged for  
34  
35  
197 1 min at 11,000 g. The washing steps were performed following the manufacturer's instructions. RNA was  
36  
37  
198 eluted in 33 µL RNase free water that was incubated twice on the membrane for 1 min. The concentration  
39  
40  
199 was determined using a Nanodrop ND-1000 spectrophotometer (Thermo Fisher Scientific, Wilmington, DE,  
41  
42  
200 U.S.A.). Removal of contaminating DNA, cDNA synthesis and qPCR was performed as described previously  
43  
44  
201 (Böhm et al., 2018). The following primers were used for qPCR and transcript numbers were normalized to  
46  
47  
202 10,000 transcripts of the housekeeping gene, the growth elongation factor EF1a (Patankar et al., 2016):  
48  
49  
203 PdEF1afwd (5'-CTGTTGCAACAAGATGGA-3'), PdEF1arev (5'-CCGAAGGTGACAACCATA-3'), Pd\_ISPSfwd (5'-  
50  
51  
204 CGTCCTATTAGTCCATGCT-3'), Pd\_ISPSrev (5'-GATGGATGTTGGAGTATC-3'), PdMTPS1fwd (5'-  
53  
54  
205 TTCCAAGAATCATAAAGGCTA-3'), PdMTPS1rev (5'-AGTCATATTAAGACTC-3'), Pd-LevSynfwd (5'-  
55  
56  
206 TGCCTCCCATATTCAAGCAT-3'), Pd-LevSynrev (5'-AGGTACATGAAGCGTGAG-3'), where PdEF1 is growth  
57  
58  
207 elongation factor EF1a (NCBI accession XM\_008785500.3), Pd\_ISPS is a putative isoprene synthase (NCBI  
60  
61  
62  
63  
64  
65

208 accession XM\_008781287.2) and Pd\_MTPS1 is a putative monoterpene synthase (NCBI accession  
1  
209 XM\_026807289.1). Pd\_ISPS primers were designed for the putative date palm isoprene synthase  
3  
4  
210 (TRINITY\_GG\_87144\_c19\_g1\_i1.p1 from Helmholtz II experiment, unpublished). ISPS transcripts were  
5  
6  
211 normalized to 10000 molecules of HKG EF1 $\alpha$  using standard curves calculated for individual PCR products.

212

10

11

213 **Measurement of foliar traits and pigments**

12

13

214

15

215 After the leaf gas exchange measurements, five leaf discs of 0.8 cm diameter per the same target leaf (one  
17

18

216 leaf, 2<sup>nd</sup> fully expanded leaves, one to two plants per plot) were collected by using a leaf punch (Fujiwara  
20

217 Scientific Company Co., Ltd., Tokyo, Japan), and weighted by a scale (Model Bp110, Sartorius weighing  
22

23

218 technology, Germany) in order to calculate fresh weight of the samples (FW). They were then dried at 70°C  
24

25

219 for at least 72 h in the oven. Leaf mass per area (LMA) was calculated as a ratio of dry mass (DW) and area  
27

220 (LA) of each leaf. Leaf water content was calculated as  $LWC (\%) = (FW - DW) / FW \times 100$ .  
29

30

221

31

32

222 Other leaf samples (ca. 3 g) of each target leaf (one leaf, 2<sup>nd</sup> fully expanded leaves, one plant per plot) were  
34

223 harvested, immediately flash-frozen with liquid nitrogen and stored at -80°C until leaf pigment analysis.  
36

37

224 Leaf pigments were determined by ultra high performance liquid chromatography (UHPLC) using a Dionex  
39

40

225 UltiMate 3000 system equipped with an Acclaim 120 C18 column (5- $\mu$ m particle size, 4.6-mm internal  
41

226 diameter  $\times$  150-mm length) maintained into a Dionex TCC-100 column oven at 30 °C, and a Dionex UVD  
43

44

227 170U detector (Thermo Scientific, Waltham MA, USA; Cotrozzi et al., 2018b). Leaf material (50 mg fresh  
46

228 weight, FW) was homogenized in 1 mL of 100% HPLC-grade methanol and incubated overnight at 5 °C in  
48

229 the dark. The sample supernatants were filtered through 0.2  $\mu$ m Minisart® SRT 15 aseptic filters. The  
50

51

230 pigments were eluted using 100% solvent A (acetonitrile/methanol, 75/25, v/v) for the first 14 min to elute  
53

231 xanthophylls (neoxanthin, Neo; violaxanthin, Vio; antheraxanthin, Ant; lutein, Lut; zeaxanthin, Zea; in order  
55

232 of elution), followed by a 1.5-min linear gradient to 100% solvent B (methanol/ethylacetate, 68/32, v/v),  
56

233 which was pumped for 14.5 min to elute chlorophyll b (Chl b) and chlorophyll a (Chl a) and  $\beta$ -carotene ( $\beta$ -  
60

61

62

63

64

65

234 car), followed by 2-min linear gradient to 100% solvent A. The flow rate was 1 ml min<sup>-1</sup>. The column was  
1  
235 allowed to re-equilibrate in 100% solvent A for 1 min before the next injection. The pigments were  
3  
236 detected by their absorbance at 445 nm. To quantify the pigment content, known amounts of pure  
4  
5  
6  
237 standards were injected into the UHPLC system and an equation correlating the peak area to pigment  
8  
238 concentration was formulated. The data were processed using the Thermo Scientific Dionex Chromeleon 7  
10  
11  
239 Chromatography Data System software. Total chlorophyll content (Chl<sub>TOT</sub>) was calculated as Chl a + Chl b.  
12  
13  
240 Total carotenoid content (Car<sub>TOT</sub>) was calculated as Neo + Vio + Ant + Lut + Zea + β-car, while the  
15  
16  
241 xanthophyll cycle pigment content (VAZ) was calculated as Vaz + Ant + Zea. The de-epoxidation state (DEPS)  
17  
18  
242 was calculated as (Ant + Zea)/VAZ.  
20  
21  
243

#### 244 ***Assessment of growth and biomass***

245  
27  
246 Plant height, number of leaves and base diameter were recorded at the beginning and the end of the  
29  
30  
247 experiment with a ruler and a caliper with 1-mm accuracy. Total above- and below-ground biomass of all  
31  
32  
248 plants was harvested at the end of the experiment and put in the oven at 70 °C until constant weight was  
34  
35  
249 reached (ab. 72 hours). After that, DW of each plant organ was determined by a scale (Model Bp110,  
36  
37  
250 Sartorius weighing technology, Germany).  
38  
39

#### 40 41 42 ***Statistical analysis***

43  
44  
45  
46  
47  
254 Data from the plants in each plot were averaged and the average was used as statistical unit, i.e. N = 3  
48  
49  
255 plots. Data were tested for normal distribution and homogeneity of variance by Smirnov and Levene tests,  
50  
51  
256 respectively. The effects of O<sub>3</sub> on the linear relationship between g<sub>s</sub> and VPD were tested by an analysis of  
53  
54  
257 covariance (ANCOVA). To assess the effect of O<sub>3</sub> and measurement time on A and g<sub>s</sub>, we applied a two-way  
55  
56  
258 analysis of variance (ANOVA). For the other parameters, the effect of O<sub>3</sub> was tested by one-way ANOVA  
58  
59  
60  
61  
62  
63  
64  
65

259 followed by Tukey's multiple comparison test. All statistical tests were carried out by R software (R 3.5.1: R  
1  
260 Core Team, 2018).

261

## 262 Results

263

264

### 264 *Foliar traits and pigments*

265

266

266 Date palms showed LMA values in the range of 119 to 133 g m<sup>-2</sup> (Tab. 1). There were no significant effects

297

of O<sub>3</sub> on LMA, while LWC was increased by O<sub>3</sub>. In fact, LWC values were significantly higher in 2 × AA than in AA plants (+19%).

Contents of Chl<sub>TOT</sub> and Car<sub>TOT</sub> significantly decreased only under 1.5 × AA, compared with AA (-22 and -32%, respectively), while VAZ decreased under both 1.5 × AA and 2 × AA (ca. -30%; Tab. 1). Lut values were 26% lower under 1.5 x AA than under 2 x AA, but there were no significant difference comparing these enriched O<sub>3</sub> concentrations with AA. No significant O<sub>3</sub> effects were found on Chl a/b ratio, β-car, and DEPS.

The daily measurements of leaf gas exchange indicate a significant effect of O<sub>3</sub> on A and g<sub>s</sub> (Tab. 2). Only the highest 2 × AA O<sub>3</sub> treatment induced a significant decline of A (-51% on July 23<sup>rd</sup> and -48% on July 30<sup>th</sup>) and g<sub>s</sub> (-57% on July 23<sup>rd</sup> and -59% on July 30<sup>th</sup>) relative to AA, which occurred only in the morning, although the interaction of daytime and O<sub>3</sub> treatment was not significant. The responses of g<sub>s</sub> to VPD are shown in Fig. 2. Stomatal conductance decreased with increasing VPD at AA and 1.5 x AA treatments. An ANCOVA test revealed that the y-intercept of the relationship between g<sub>s</sub> and VPD was lower in 1.5 x AA compared to the control (AA). There was no statistically significant relationship between g<sub>s</sub> and VPD at the highest

284 level of O<sub>3</sub> treatment (2.0 x AA). Dark respiration rate (R<sub>n</sub>) was significantly lower in AA than in 1.5 AA and 2  
1  
285 x AA plants (-28% and -36%, respectively) (Fig. 3).

286  
287 Parameters of the stomatal conductance model are shown in Table S1 and Fig. S1. The maximum stomatal  
288 conductance to O<sub>3</sub> (g<sub>max</sub>) value was set to 73 mmol O<sub>3</sub> m<sup>-2</sup> PLA s<sup>-1</sup> as 95<sup>th</sup> percentile of g<sub>sto</sub> measurements  
289 (Table S1, Fig. S1). The minimum stomatal conductance (f<sub>min</sub>) value was set to 0.06 (fraction) corresponding  
290 to the 5<sup>th</sup> percentile values of the stomatal conductance recorded throughout the measurements. Stomatal  
291 response to light (f<sub>light</sub>) showed a typical saturation curve with a light saturation point above 2000 μmol m<sup>-2</sup>  
292 s<sup>-1</sup> (Fig. S1a). The f<sub>O<sub>3</sub></sub> indicates that O<sub>3</sub> decreased stomatal conductance by 0.31% per unit O<sub>3</sub> concentration  
293 (ppb) in date palm leaves (Fig. S1b). The optimal temperature for stomatal opening was 27 °C (Fig. S1c).  
294 VPD higher than 2.6 kPa induced stomatal closure (Fig. S1d).

### 296 **Chlorophyll *a* fluorescence**

297  
298 At ambient O<sub>3</sub> level, the induction curve was significantly higher than in the palm leaves exposed to  
299 elevated O<sub>3</sub> levels after 300 μs (Fig. S2). The curves of leaves exposed to 1.5 x AA and 2 x AA O<sub>3</sub> exposure  
300 exhibited a similar pattern. The relative variable fluorescence ΔV showed marked differences between the  
301 AA controls and the two elevated O<sub>3</sub> treatments (Fig. S3a), with the biggest differences within the O-J-  
302 phase and the J-I-phase and a lower difference within the I-P-phase, but without a distinct peak at the J-  
303 Step and the I-Step (marked as ΔV<sub>J</sub> and ΔV<sub>I</sub>). This presentation of fluorescence kinetics showed only a small  
304 difference between both groups of O<sub>3</sub> treated leaves at 150 μs compared to the AA group (Fig. S3b). On the  
305 other hand, marked differences between the control group at ambient O<sub>3</sub> and the two groups exposed to  
306 1.5 and 2 times enhanced O<sub>3</sub> concentrations were identified in ΔW<sub>O<sub>3</sub></sub> (Fig. S3c) with a peak marked as ΔW<sub>K</sub>  
307 at an average time of 500 μs. At the beginning of the fluorescence kinetics after 150 μs of illumination,  
308 values at the L-Step were similar between AA and O<sub>3</sub> treatments (Fig. 4a). In addition, marked differences in  
309 the extent and range of the resulting values at the K-Step (t = 300 to 600 μs) were observed between O<sub>3</sub>

310 treatments and AA, with mostly positive values indicating that the fluorescence level of O<sub>3</sub> treated date  
1  
311 palm leaves at this step was higher than in AA (Fig. 4b). The variable fluorescence levels at step J (t = 2 ms)  
3  
312 and I (t = 30 ms) also showed marked differences between O<sub>3</sub> treated plants and the AA group (Fig. 4c,d).  
5  
6

313  
8

314 The quantum yield of photosystem II ( $\phi_{Po}$ ) showed statistically significant differences between AA and  
10  
315 leaves of plants growing at 1.5 x AA and 2 x AA, but no differences were found between 1.5 x AA and 2 x AA  
12  
316 (Fig. 5a). The same findings were observed for the performance index PI total (Fig. 5b) and for the number  
15  
317 of reaction centers per absorption (10RC/ABS, Fig. 5d). One-way ANOVA revealed a significant difference ( $p$   
17  
318 < 0.05) between AA and 1.5 x AA for the energy dissipation per active reaction center chlorophyll DI<sub>0</sub>/RC  
20  
319 (Fig. 5c). However, there were no statistically significant differences between AA and 2 x AA as well as  
22  
320 between 1.5 x AA and 2 x AA for this parameter.  
24  
25

321  
27

### 322 **Volatile organic compounds**

29

30  
323  
31

324 Isoprene emission was significantly impaired by both elevated O<sub>3</sub> treatments (-58% at 1.5 x AA and -50% at  
34  
325 2 x AA), while the relative expression of isoprene synthase transcripts showed a large variability and no  
36  
326 clear response to O<sub>3</sub> (Fig. 6a,b). Date palm emitted also small amounts of monoterpenes such as  $\alpha$ -pinene,  
39  
40  
327  $\beta$ -pinene, octanal, nonanal, camphor, iso-borneol (data not shown), whose emission was stimulated in 2 x  
41  
328 AA plants, so that the emission of total VOCs decreased only at 1.5 x AA (-57% relative to AA) (Fig. 6c,e).  
44  
329 Also the relative expression of monoterpene synthases was very variable and the increases at 2 x AA were  
46  
330 not statistically significant (Fig. 6d). Isoprene emission was correlated positively with net photosynthesis  
48  
331 (Fig. 7a) and negatively with intercellular CO<sub>2</sub> concentration (C<sub>i</sub>) (Fig. 7b). However, such correlations were  
51  
332 not found in monoterpene emission.  
53

54  
333  
55

### 334 **Growth and biomass**

58

59  
335  
60

61  
62  
63  
64  
65

336 Plant height, number of leaves and base diameter were not affected by O<sub>3</sub> treatments (data not shown).  
1  
337 However, during the 3-month experiment, the plants significantly increased in diameter from the beginning  
3  
338 of the experiment (2.06 ± 0.31 cm) to the end (2.80 ± 0.46 cm), while plant height (107 ± 8.9 cm vs. 111 ±  
5  
339 9.4 cm) and number of leaves (5.5 ± 1.0 vs. 6.0 ± 0.8) were unaltered. Above- and below-ground biomass  
8  
340 decreased with increasing O<sub>3</sub> treatments, but the effect was significant only for the 2 x AA roots relative to  
10  
341 AA roots (-36%) (Fig. 8a,b).  
12

1342

## 343 Discussion

1344

345 The growth conditions at the study site were suitable for date palm as suggested by the increase in base  
22  
346 diameter over the experiment. For instance, the average diurnal air temperature was 19.5/27.8/29.2/30.1  
24  
347 °C in May/June/July/August, i.e. in the range of values in Riyadh, Saudi Arabia (31.1/33.7/34.8/32.7 °C), that  
27  
348 is one of the major area of date palm distribution and cultivation (Aleid et al., 2015). The stomatal  
29  
349 conductance model showed that the optimal temperature for stomatal opening was 27 °C in this date palm  
31  
350 cultivar. The O<sub>3</sub> levels were realistic as they well simulated the conditions in Riyadh. For instance, the O<sub>3</sub>  
34  
351 peaks in May/June/July/August were 72/110/105/92 ppb at the ozone FACE and 66/95/98/90 ppb in  
36  
352 Riyadh (Butenhof et al., 2015). Such realistic O<sub>3</sub> levels translated into very high values of AOT40. At the end  
38  
353 of the experiment, in fact, the date palms were exposed to AOT40 levels that were 4 (AA), 9.2 (1.5 x AA)  
41  
354 and 12.4 (2 x AA) times higher than the critical level recommended to protect plants from O<sub>3</sub> injury, i.e. 5  
43  
355 ppm h (CLRTAP, 2014).  
46

356

### 357 *Photosynthetic responses to ozone exposure*

358

359 Elevated O<sub>3</sub> exposure induced significant negative effects on date palm photosynthesis in the morning,  
55  
360 especially at the highest 2 x AA O<sub>3</sub> level. Stomatal resistance to CO<sub>2</sub> transport may be considered as a factor  
58  
361 to limit photosynthetic activity in elevated O<sub>3</sub> (Kitao et al., 2009; Hoshika et al., 2020b). In fact, stomatal  
60

362 closure due to elevated O<sub>3</sub> exposure was observed in the morning for date palm plants. However, such  
1  
363 stomatal closure cannot be found in the afternoon, suggesting that the closing response induced by  
3  
364 atmospheric humidity deficit may over-rule stomatal sensitivity to O<sub>3</sub>. Interestingly, the highest O<sub>3</sub>  
4  
5  
6  
365 treatment (2 x AA) induced a loss of stomatal response to VPD. It has been shown that O<sub>3</sub> exposure causes  
8  
366 an impairment of efficient stomatal control of gas exchange, i.e. stomatal sluggishness (Paoletti, 2005;  
10  
367 Hoshika et al., 2019, 2020a). Hoshika et al. (2019) demonstrated that the sluggish response of stomata was  
11  
12  
13  
368 attributed to ethylene emission. However, the mechanisms are still under investigated.

15  
16  
369  
17  
18  
370 A reduction of photosynthesis due to elevated O<sub>3</sub> exposure may be caused by not only stomatal but also  
19  
20  
371 biochemical limitation (Hoshika et al., 2020b). In fact, an impairment of the gas exchange was in  
21  
22  
372 accordance with the overall reduction of photosynthetic pigments (i.e. Chl<sub>TOT</sub> and Car<sub>TOT</sub>) which play a  
23  
24  
25  
373 crucial role in light harvesting for photosynthesis. The degradation of chlorophyll and carotenoids was  
26  
27  
374 similarly found in O<sub>3</sub> exposed leaves due to oxidative-stress destruction (Watanabe et al., 2013; Cotrozzi et  
28  
29  
30  
375 al., 2018a). Fast chlorophyll fluorescence kinetics of dark-adapted samples indicated that O<sub>3</sub> exposure  
31  
32  
376 strongly affected photosynthetic electron transport in date palm leaves. Ozone exposure decreased the  
33  
34  
377 maximum quantum efficiency of PSII ( $\phi_{PO}$ ;  $F_V/F_M$ ), the average performance ( $PI_{TOT}$ ), and the activity of PSII  
35  
36  
37  
378 RCs as reported before (Contran et al., 2009; Bussotti et al., 2011; Pellegrini et al., 2011; Salvatori et al.,  
38  
39  
40  
379 2013; Zhang et al., 2018b). Recently, we developed a new spectroscopic model to predict these  
41  
42  
380 fluorescence parameters in date palm (Cotrozzi et al., 2020). For a detailed analysis of hyperspectral  
43  
44  
381 parameters *see* Cotrozzi et al. (2020). In addition, our results show clear differences within the OJ-phase  
45  
46  
47  
382 between the control AA group and the two groups growing at elevated O<sub>3</sub>. The differences in the  
48  
49  
383 functionality of PSII of date palms exposed to elevated O<sub>3</sub> were not caused by a lesser connectivity between  
50  
51  
384 PSII units, since there was no significant difference of the fast fluorescence kinetics at 150  $\mu$ s between  
52  
53  
385 plants exposed to either elevated O<sub>3</sub> treatment or AA. Many studies demonstrated that inactivation of the  
54  
55  
386 oxygen evolving complex (OEC) is a typical reaction of plants to abiotic stress like heat stress or drought  
56  
57  
387 (Oukarroum et al., 2007; Oukarroum et al., 2009; Hu et al., 2020). This inactivation leads to an inhibition of  
58  
59  
60  
61  
62  
63  
64  
65

388 electron transport by releasing the manganese cluster, the main component of OEC, thereby causing an  
1  
389 imbalance between the electron flow from the OEC to the RCs (Chen et al., 2016). Studies on the effect of  
3  
390 elevated O<sub>3</sub> on the photosynthetic performance of several woody species such as beech, oak and poplars  
5  
391 showed that inactivation or breakdown of OECs represent an early response to O<sub>3</sub> stress (Bussotti et al.,  
8  
392 2011; Desotgiu et al., 2013), as also observed in our experiment.

11  
393  
13  
394 Differences were not only found within the OJ-phase, but also the JI-phase and to a lesser extent the IP-  
15  
395 phase. The JI-phase is related to the redox state of the plastoquinone pool (Tóth et al., 2007). Its redox is  
17  
396 affected by oxidative stress caused by O<sub>3</sub>, probably via the plastidic NADH-plastoquinone oxidoreductase  
20  
397 (Ndh) complex (Guéra et al., 2005). Thus, the present findings suggest that oxidative stress due to O<sub>3</sub>  
22  
398 exposure led to disturbances in the plastoquinone pool of the photosynthetic electron transport chain. The  
24  
399 IP-phase of the fluorescence transient is related to photosystem-I (PSI) activity (Schansker et al. 2005),  
27  
400 indicates the rate of reduction of ferredoxin (Cascio et al., 2010) and is thought to constitute a measure of  
29  
401 PSI electron acceptors (Tsimilli-Michael and Strasser, 2008; Živčák et al., 2014). Experiments with *Quercus*  
31  
402 *ilex* L. and *Arbutus unedo* L. showed that the activity of PSI has a key role in O<sub>3</sub>-mediated oxidative stress  
34  
403 (Mereu et al., 2011). Bussotti et al. (2011) reported that the main impact of O<sub>3</sub>-mediated oxidative stress  
36  
404 was in and beyond PSI for poplar hybrids. However, our results suggest that date palms were less sensitive  
39  
405 to O<sub>3</sub> in the last part of the photosynthetic electron transport chain, with only a minor effect on PSI activity.

#### 407 *Isoprene and monoterpene responses to ozone exposure*

46  
408  
48  
49  
409 Volatile isoprenoids such as isoprene and monoterpenes are among the most abundant and reactive  
50  
51  
52 biogenic VOCs produced by plants (Guenther et al., 2012). Isoprene-emitting species occur in many plant  
53  
54 taxa across many functional types, but they are more often found in woody plant species including palms  
55  
56 (Kesselmeier and Staudt, 1999). Our date palms emitted low amounts of isoprene (on average  $8.4 \pm 0.8$  ng  
57  
58 m<sup>-2</sup> s<sup>-1</sup> in AA) relative to literature data for this species ( $\sim 27$  ng m<sup>-2</sup> s<sup>-1</sup> in Arab et al., 2016, still at 30 °C but  
59  
60  
61  
62  
63  
64  
65

414 under 1200  $\mu\text{mol m}^{-2} \text{s}^{-1}$  PAR). Tree species on average emit 22-79  $\text{ng m}^{-2} \text{s}^{-1}$  isoprene at or near standard  
1  
415 conditions, but different leaf environments and measurement techniques may significant affect such values  
3  
416 (Geron et al., 2001). Isoprene emission from date palm leaves declined at both 1.5 and 2 x AA relative to  
5  
6  
417 AA, while the relative expression of isoprene synthase transcripts did not respond to  $\text{O}_3$ . Photosynthesis  
8  
418 and isoprene emission declined in tandem, which is supported by a meta-analysis of isoprenoid responses  
10  
419 to abiotic factors including  $\text{O}_3$  (Feng et al., 2019).  
12

13  
420  
15  
421 Interestingly, date palm also produced low amounts of total monoterpenes (on average  $1.8 \pm 0.3 \text{ ng m}^{-2} \text{ s}^{-1}$   
17  
422 in AA), whose emission was stimulated in 2 x AA leaves, although an increase in the relative expression of  
20  
423 monoterpene synthase transcripts in 2 x AA leaves was not statistically significant. The stimulation of  
22  
424 monoterpene emission by  $\text{O}_3$  exposure was similarly reported mainly in evergreen species by the meta-  
24  
425 analysis (Feng et al., 2019). The monoterpene emission from date palm leaves in elevated  $\text{O}_3$  was not  
27  
426 dependent on photosynthesis. The uncoupling of monoterpene emission from photosynthesis may be a  
29  
427 hormetic response to the initial stage of stress (Agathokleous et al., 2018).  
31

32  
428  
34  
429 *Biomass responses to ozone exposure*  
36

37  
430  
39  
431 A leaf-level photosynthetic activity may be closely related to plant growth. As a result of  $\text{O}_3$ -induced  
41  
432 damage to photosynthetic activity, biomass accumulations are usually limited (Li et al., 2017; Gao et al.,  
43  
433 2017). In date palm, however, plant height, number of leaves, base diameter and above-ground biomass  
46  
434 were not significantly affected by elevated  $\text{O}_3$  exposure, while root biomass was reduced only at the  
48  
435 highest 2 x AA level. It is well known that a reduction of photosynthate allocation to roots is one of the first  
50  
51  
436 steps of  $\text{O}_3$  injury to plants (Carriero et al., 2015; Mrak et al., 2019). Decrease in root biomass due to  $\text{O}_3$  was  
53  
437 reported in approx. 40% of studies on trees according to a meta-analytic review (Agathokleous et al., 2016).  
55

Ozone exposure did not significantly affect most of the growth parameters, although 2 x AA O<sub>3</sub> exposure reduced below-ground biomass. These results indicate that this date palm cultivar may be intermediately susceptible to O<sub>3</sub>. In fact, evergreen species such as date palm is more resistant to O<sub>3</sub> than deciduous species (Feng et al., 2018), because larger availability of cell walls implies larger apoplastic substrate for O<sub>3</sub> detoxification (Moldau, 1998). However, plant resistance to O<sub>3</sub> may depend not only on leaf habit (deciduous and evergreen) but also various physiological factors (Feng et al., 2018).

A well-known factor mitigating O<sub>3</sub> susceptibility of plant species is low stomatal conductance and, thus, restricted stomatal O<sub>3</sub> uptake (Reich, 1987). Here we present a Jarvis-type stomatal conductance model for estimating the maximum g<sub>s</sub> in this species and estimated a g<sub>max</sub> value (73 mmol O<sub>3</sub> m<sup>-2</sup> s<sup>-1</sup>) that is in line with the values of desert shrubs and in the lower range of global values found in a meta-analysis of g<sub>s</sub> in woody plants (Hoshika et al., 2018). Although our g<sub>max</sub> value was slightly higher than previous observations of g<sub>s</sub> in the same species (40 to 50 mmol O<sub>3</sub> m<sup>-2</sup> s<sup>-1</sup>, Du et al., 2018; Kruse et al., 2017, 2019), a previous Jarvis-type g<sub>s</sub> modeling study on *P. dactylifera* found a much higher g<sub>max</sub> in a different cultivar (ab. 200 mmol O<sub>3</sub> m<sup>-2</sup> s<sup>-1</sup> in cv. Medjool, Sperling et al 2014). Stomatal conductance of different date palm cultivars may differ considerably (Al-Jabr et al., 2007), thus suggesting that further cultivar-specific studies are also needed. Such a low capacity of stomatal O<sub>3</sub> uptake implied an uncoupling of AOT40 and POD1 values. In fact, AOT40 values at the end of the experiment were 2.3 and 3.1 times higher than AA, while POD1 values were only 1.6 and 1.9 times higher in 1.5 x AA and 2 x AA, respectively, which well synthesizes the elevated stomatal defense capacity of date palm from elevated atmospheric concentrations of O<sub>3</sub>. As a matter of fact, the function f<sub>O<sub>3</sub></sub> indicates that O<sub>3</sub> decreased stomatal conductance by 0.31% per unit O<sub>3</sub> concentration (ppb) in date palm. As a result, 2 x AA O<sub>3</sub> exposure reduced g<sub>s</sub> by 46%. Ozone-induced stomatal closure may act as an avoidance response to reduce a possible O<sub>3</sub> damage to plants (Hoshika et al., 2020a).

465 Stomatal closure, however, may also cause excess light energy and production of reactive oxygen species  
1  
466 (ROS), which raises susceptibility to photoinhibitory damage (Takagi et al., 2017; Giudi et al., 2019). It  
3  
467 seems that date palm plants adopted a major protective mechanism to reduce the absorption of excitation  
4  
5  
6  
468 energy and preserve photosystems from photoinhibition through a reduction in the number of light-  
8  
469 harvesting antennae rather than in the chlorophyll antenna size (as confirmed by the unchanged values of  
10  
11  
470 Chl a/b ratio; Cotrozzi et al., 2018b). Indeed, no other differential responses in leaf pigment parameters  
12  
13  
471 were observed between plants exposed to 1.5 and 2 x AA levels. Although a reduction of VAZ was  
15  
16  
472 observed, other well-known photo-protective mechanisms (i.e. changing chlorophyll composition,  
17  
18  
473 increasing  $\beta$ -car levels and DEPS; Esteban et al., 2015) were not activated, indicating that a re-organization  
20  
21  
474 of the photosynthetic apparatus did not occur and confirming the intermediate susceptibility to O<sub>3</sub> of date  
22  
23  
475 palm.  
24

25  
26  
27  
477 The ability of increasing dark respiration under O<sub>3</sub> stress may have also contributed to mitigate the  
29  
30  
478 susceptibility of date palm. While the respiratory CO<sub>2</sub> loss is a major cause for the reduction of carbon gain  
31  
32  
479 due to elevated O<sub>3</sub> (Zhang et al., 2018a; Podda et al., 2019), dark respiration is important in the  
34  
35  
480 biosynthetic processes of growth and maintenance, which raises a metabolic capacity for repair of  
36  
37  
481 damaged tissues and detoxification especially under abiotic and/or biotic stress (Weraduwege et al., 2011).  
38  
39  
482 In fact, no oxidative damage (assessed in terms of lipid peroxidation) was observed under both increased  
41  
42  
483 O<sub>3</sub> concentrations, with a slight decrease of hydrogen peroxide reported only under 2 x AA (Arab et al. in  
43  
44  
484 prep). This response was due to an ability of date palm to regulate its major enzymatic and non-enzymatic  
46  
47  
485 antioxidants. In particular, the decreased Car<sub>tot</sub> (only under 1.5 x AA) and VAZ values indicate that these  
48  
49  
486 compounds could be consumed by the cell in order to counteract the possible reactive oxygen species  
50  
51  
487 generation by preventing their peroxidation action. Is it known that they are involved in non-photochemical  
53  
54  
488 quenching mechanisms, thus reducing the risk of photo-oxidative stress (Niinemets et al., 2003). Based on  
55  
56  
489 relative physical-chemical features and intra-cellular distribution, these antioxidant compounds may serve  
57  
58  
490 distinct and complementary functions (Close and Beadle, 2003).

If isoprene emission confers protection to date palm against O<sub>3</sub> injury (Loreto and Velikova, 2001; Velikova et al., 2005), we may expect that synthesis and emission of isoprene increased with increasing O<sub>3</sub> exposure. However, our results contrasted with this hypothesis, suggesting that isoprene emission from date palm leaves may have not contributed to the protection against O<sub>3</sub> stress. A recent review questioned the common belief that isoprene has immediate, physical effects on plants such as changing membrane properties or quenching ROS (Lantz et al., 2019), because it is highly volatile and does not dissolve into cellular components in great quantity (Harvey et al., 2015). Interestingly, on the other hand, O<sub>3</sub> increased monoterpene emission, which may be also considered as a factor to protect plants from O<sub>3</sub> damage (Fares et al., 2008). While isoprene and monoterpenes share common biosynthetic pathways, monoterpenes are usually stored after synthesis in special organs, such as resin ducts or glands (Kesselmeier and Staudt, 1999). So far, it is unclear whether O<sub>3</sub> may have a direct effect on the storage pools of monoterpenes, and also the number of O<sub>3</sub> studies on monoterpene-emitting species is limited (e.g. Carriero et al., 2016; Mochizuchi et al., 2017). Hadacek et al. (2011) proposed that non-linear hormetic effects regulate the responses of stored secondary metabolites to abiotic factors, and that the reduction of ROS is a key step of the hormetic effects caused by these compounds. ROS are known to be stimulated by O<sub>3</sub> exposure (Pellegrini et al., 2019; Podda et al., 2019) as also shown in our date palms (data not shown). Overall, our results warrant more research on the redox chemistry of terpenoids under O<sub>3</sub> stress.

## Conclusions

This is the first experiment on date palm responses to chronic, realistic O<sub>3</sub> exposure. Significant declines of several gas exchange parameters and root biomass occurred only at the highest 2 x AA O<sub>3</sub> level. Some variables that are usually known as early responses to O<sub>3</sub> stress, responded already at 1.5 x AA. Isoprene emission did not appear to contribute to date palm O<sub>3</sub> tolerance as it declined at both elevated O<sub>3</sub> levels. In contrast, monoterpene emission was stimulated at 2 x AA and its O<sub>3</sub> responses should be further evaluated.

517 The major defense mechanisms that emerged from this study were avoidance of O<sub>3</sub> stress (i.e. exclusion of  
1  
518 O<sub>3</sub> entry by low maximum stomatal conductance to O<sub>3</sub> [73 mmol O<sub>3</sub> m<sup>-2</sup> s<sup>-1</sup>] and O<sub>3</sub>-induced stomatal  
3  
519 stomatal closure) and high capacity of catabolizing metabolites for detoxification and repair as indicated by  
4  
520 increased dark respiration. We thus conclude that this date palm cultivar was intermediately susceptible to  
6  
521 O<sub>3</sub>, but further studies with different cultivars are recommended as date palm cultivars may significantly  
10  
522 differ in their physiological traits such as stomatal conductance. These results are needed for a proper O<sub>3</sub>  
11  
12  
13  
523 risk assessment in the areas where *P. dactylifera* grows.

Whiskers: 1,5 x IQR, dots: outliers, cross: average, line: median; green dotted line at  $y = 0$ : reference value at ambient ozone level;  $n = 3$  plots. (a)  $\Delta W_L$  difference of variable fluorescence  $\Delta W_{OK}$ , at the L-Step at  $t = 150 \mu s$ . (b) difference of variable fluorescence  $\Delta W_{OK}$ , at the K-Step  $t = 300-600 \mu s$ . (c) difference of variable fluorescence  $\Delta V$ , at the J-Step  $t = 2 ms$ . (d) difference of variable fluorescence  $\Delta V$ , at the I-Step  $t = 30 ms$ .

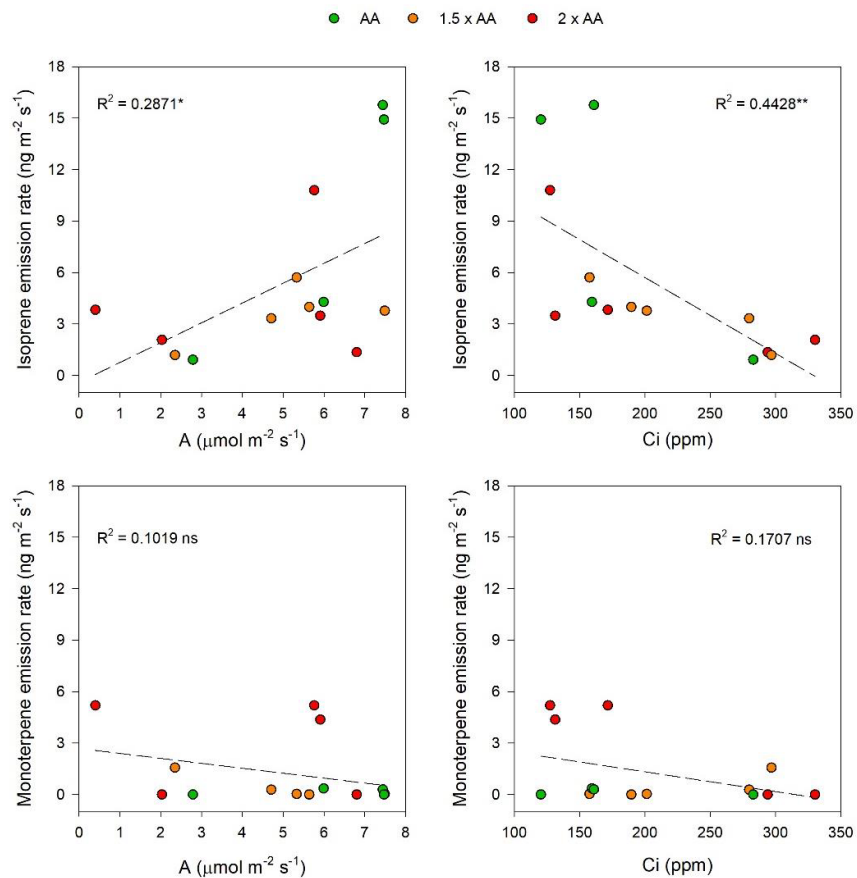

**Fig. 5.** Effect of different ozone levels on date palms on (a) maximum quantum yield for primary photochemistry  $\phi_{Po}$  (b) the performance index  $PI_{TOT}$ , (c) energy dissipation per active reaction centres  $DI_0/RC$ , (d) reaction centres per absorption  $10RC/ABS$ . Boxplots show: Green boxes, ambient ozone level (AA); orange boxes, 1.5 x AA; red boxes, 2 x AA. Whiskers: 1,5 x IQR, dots: outliers, cross: average, line: median. Different letters show significant differences among treatments (Tukey test,  $p < 0.05$ ,  $N = 3$  plots).

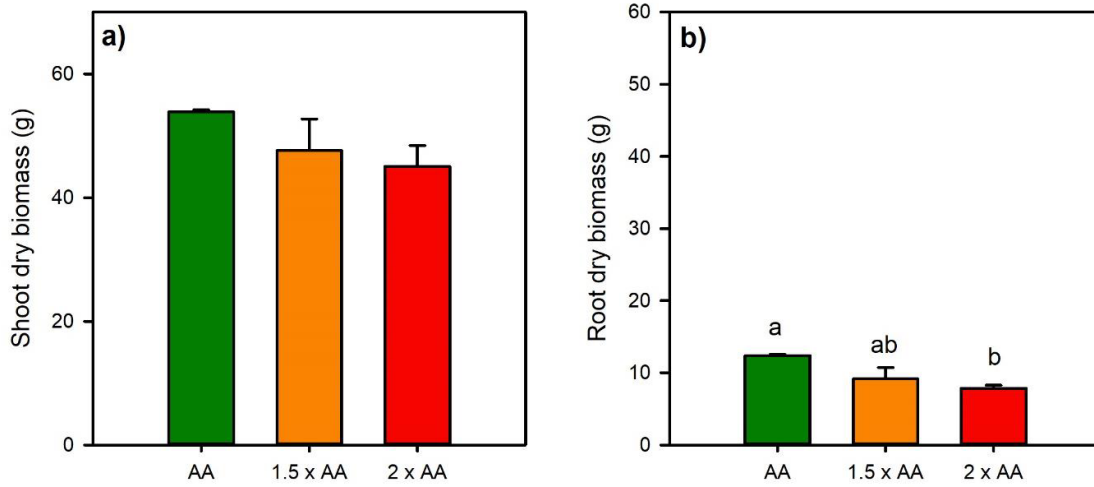

**Fig. 6** Average ( $\pm$  standard error) of isoprene emission (a), relative expression of isoprene synthase transcripts (b), monoterpene emission (c), relative expression of monoterpene synthases (d) and total volatile organic compounds (VOC) emission (e) in date palm leaves on 1-2 August. Different letters show significant effects of the ozone treatments (AA, ambient, 1.5 x AA, 2 x AA) (Tukey test,  $p < 0.05$ ,  $N = 3$  plots).

**Tab. 1.** Mass per area (LMA), water content (LWC), total chlorophyll content (Chl<sub>TOT</sub>), chlorophyll a/b ratio (Chl a/b), total carotenoid content (Car<sub>TOT</sub>), β-carotene (β-car), lutein (Lut), xanthophyll cycle pigment content (VAZ) and de-epoxidation state (DEPS) in the leaves of date palm plants grown under three levels of O<sub>3</sub> concentration (AA, ambient O<sub>3</sub> concentration, 1.5 × AA, 2 × AA). Each value is the mean ± standard error (N = 3 plots). Asterisks show the significance of ANOVA: \*\*  $p < 0.01$ , \*  $p < 0.05$ , ns denotes not significant. Different letters show significant differences among treatments ( $p < 0.05$ , Tukey test).

	LMA (g m <sup>-2</sup> )	LWC (%)	Chl <sub>TOT</sub> (μmol g <sup>-1</sup> FW)	Chl a/b	Car <sub>TOT</sub> (μmol g <sup>-1</sup> FW)	β-car (μmol g <sup>-1</sup> FW)	Lut (μmol g <sup>-1</sup> FW)	VAZ (μmol g <sup>-1</sup> FW)	DEPS (%)
