4 **Abstract** Ultraviolet radiation exerts detrimental effects on terrestrial and marine ecosystems, in
5
6 particular in polar regions where elevated solar radiation is caused by stratospheric ozone reduction.
7
8 We explored the sensitivity to ultraviolet radiation of two polar species of the ciliate *Euplotes*,
9
10 *Euplotes focardii* and *Euplotes nobilii*, in comparison with their close phylogenetic relatives
11
12 inhabiting mid-latitude and tropical waters. Results showed that the two polar species face UV
13
14 radiation more efficiently than their non-polar relatives, however by adopting different mechanisms.
15
16 While *E. focardii* survives for longer times to UV radiation, *E. nobilii* recovers faster from UV-
17
18 induced damages.

Introduction

Among the environmental factors influencing the temporal and spatial distribution of aquatic microorganisms, a dominant role is played by the intensity of ultraviolet (UV) radiation and depth of UV penetration into the water column. These factors are particularly detrimental to microbial communities [4, 16, 25, 26] because UV-radiation may cause cell-damage on several cell targets, either directly through absorption of the hazardous short-wavelength (280-320 nm) UV-B radiation, or indirectly through the generation of reactive oxygen species induced by the longer wavelength (320-400 nm) UV-A radiation [1, 15, 19, 24]. Polar organisms are particularly exposed to UV-induced cellular damage, especially those of the Antarctic regions where the continuous decline in stratospheric ozone tends to substantially increase the levels of UV-radiation [5, 6, 11, 20].

In polar ecosystems, species of the ubiquitous ciliate *Euplotes* are a very common component of marine microbial communities and their isolates can easily be adapted to grow in stable laboratory cultures [12, 13]. We used two sets of these cultures, one representative of *E. focardii*, a species endemic to Antarctic waters [22], and the other one representative of *E. nobilii*, which is distributed in both Arctic and Antarctic waters [7, 21], in order to compare polar species of *Euplotes* with their non-polar relatives in terms of their capacity to withstand UV-radiation. Based on the knowledge of phylogenetic trees of *Euplotes* species generated by matching of the small subunit (SSU)-rRNA nuclear gene sequences [8, 23], *E. quinquecarinatus* and *E. raikovi* were chosen as non-polar relatives of *E. focardii* and *E. nobilii*, respectively. From this comparison we obtained clear evidence that the polar species of *Euplotes* are either more resistant to UV exposure (*E. focardii*), or can more easily repair the UV-induced cell damages (*E. nobilii*).

Materials and Methods

Strain origin and cultivation

1
2
3
4 Collection sites of the *Euplotes* strains used in this study are presented in Table 1. The *E. focardii*
5
6 and *E. nobilii* cultures were maintained at 4 °C and the cultures of *E. quinquecarinatus* and *E.*
7
8 *raikovi* at 23 °C. All were fed with the green algae *Dunaliella tertiolecta* grown in defined salt
9
10 artificial seawater (32‰, pH 8.0). Cells were washed free of food and re-suspended in fresh sea
11
12 water for 2 days before being used in experiments.
13
14
15

16 17 18 Irradiation experiments 19

20
21
22
23 Irradiation experiments were carried out in 96-well plates using aliquots of 10,000 cells/well in 100
24
25 µl of seawater and fluorescent lamps (UVP Inc., Upland, CA, USA) of 365 nm and 15 W for UV-A,
26
27 and 302 nm and 15 W for UV-B. Any other light source was excluded throughout irradiation. The
28
29 distance between the plates and the lamps was set to 10 cm in order to expose cells at UV-A and
30
31 UV-B to average intensities of 3.90 mW/cm² and 4.00 mW/cm², respectively. The UV outputs were
32
33 monitored with a UVX Digital Radiometer (UVP Inc., Upland, CA, USA), supplied with a 365
34
35 (UVX-36) and 310 (UVX-31) nm detector placed at the same distance from the UV source as the
36
37 plates.
38
39
40
41
42

43 44 Cell viability assays 45

46
47
48
49 The cell viability was assayed according to a previously described standard protocol [2]. After the
50
51 UV irradiation, cells were incubated for 60 min in the presence of 3-(4,5-dimethylthiazol-2-yl)-2,5-
52
53 diphenyltetrazolium bromide (MTT) (10 µl/well from a 5 mg/ml solution), which is reduced to
54
55 formazan by viable cells. The reaction was stopped through the addition of DMSO to dissolve the
56
57 insoluble purple formazan, quantified by absorbance at 570 nm using a Microplate Reader 680 XR
58
59
60

1
2
3
4 Spectrophotometer (Bio-Rad, Hercules, CA, USA). The statistical significance of the data was
5
6 evaluated by combining ANOVA and Newman-Keuls Multiple Comparison post-test.
7
8
9

10 11 **Results and Discussion**

12
13
14
15
16 The sensitivity to UV-radiation of the two polar species, *E. focardii* and *E. nobilii*, was first
17
18 compared with the sensitivity of the two non-polar species, *E. quinquecarinatus* and *E. raikovi*, by
19
20 exposing equivalent cell samples to UV-A or UV-B radiation in temperature-controlled chambers
21
22 (the polar species at 4 °C and the non-polar at 23 °C), and measuring the cell viability at increasing
23
24 intervals of UV exposure. This exposure ranged from 10 min (23.32 kJ m⁻² UV dose) to 8 h
25
26 (1119.36 kJ m⁻² UV dose) for UV-A, and from 3 min (7.20 kJ m⁻² UV dose) to 5 h (720.00 kJ m⁻²
27
28 UV dose) for UV-B. As shown in Fig. 1, viability in all four species progressively decreased after
29
30 UV exposure. However, their survival rates appeared to be markedly different. *E. focardii* was
31
32 much more resistant than any other species to both UV-A and UV-B radiation; its viability was
33
34 approximately 70% at 3 h of UV-A exposure, remaining above 65% even at 8 h of UV-A exposure,
35
36 and was still above 50% at 30 min of exposure to the more harmful UV-B radiation. In contrast, *E.*
37
38 *quinquecarinatus* (the *E. focardii* non-polar relative) was the least resistant species, as the majority
39
40 of cells were no longer viable after 3 h of UV-A and 30 min of UV-B radiation. However, no
41
42 significant variations in survival rates were detected between *E. nobilii* and *E. raikovi*: the values of
43
44 viability of both species were about 40% at 3 h of UV-A exposure, and 20-30 % at 30 min of UV-B
45
46 exposure.
47
48
49
50
51
52

53
54 In a second set of experiments, we assessed the cell capacity to recover from UV-induced
55
56 damage by exposing cells to the sub-maximal/maximal doses of UV-A or UV-B radiation (3 h
57
58 equivalent to 419.76 kJ m⁻² for UV-A, and 1 h equivalent to 144.00 kJ m⁻² for UV-B) and
59
60 comparing the cell viability immediately after UV exposure and at 6 h of recovery in the dark. As

1
2
3
4 shown in Fig. 2, while UV-B radiation was indistinctly lethal to all four species, UV-A radiation
5
6 was lethal to all species except *E. nobilii*. Contrary to viability rates in *E. focardii* and the two other
7
8 non-polar species, which did not recover from the negative effects of the UV-A radiation, the *E.*
9
10 *nobilii* viability rate nearly doubled at 6 h of rescue in the dark by increasing from 34% to 60% in
11
12 the Antarctic strains and from 44% to 83% in the Arctic ones.

13
14
15 The conclusive evidence that arises from these results is that the polar species of *Euplotes*
16
17 withstand UV radiation much more efficiently than their phylogenetically non-polar relatives, albeit
18
19 by apparently adopting different strategies. While *E. focardii* appears to be strongly protected
20
21 against direct UV radiation and unable to recover from UV damage, *E. nobilii* seems to be poorly
22
23 protected against UV radiation and counterbalances this scarce protection with a remarkable
24
25 capacity to quickly repair UV damage. We suggest that these differences between *E. focardii* and *E.*
26
27 *nobilii* in withstanding UV radiation reflect differences in the adaptive evolution of these two
28
29 species to the polar environment.
30
31
32
33

34
35 *E. focardii* is a strictly psychrophilic species endemic to the Antarctic waters [22], characterized
36
37 by an unusually reduced spectrum of transcriptional responses of its heat-shock protein (*hsp-70*)
38
39 genes [10]. This suggests a close correlation between the ancient adaptation of *E. focardii* to the
40
41 UV-radiation in Antarctica and the evolution of a specific defense mechanism based on the
42
43 constitutive synthesis of photo-protective compounds such as the sunscreen mycosporine-like
44
45 amino acids [9]. Enzymes of the shikimate pathway responsible for the production of these amino
46
47 acids are ancient in the evolution of eukaryotes [14], and the finding of these enzymes are widely
48
49 distributed in aquatic organisms [3], including ciliates [14, 17, 18], credits the hypothesis that *E.*
50
51 *focardii* relies on them (rather than on the activity of the *hsp-70* genes) to prevent the deleterious
52
53 effects of UV radiation.
54
55
56

57
58 Differently from *E. focardii*, *E. nobilii* is not endemic to Antarctica, but it is a bipolar species
59
60 represented by Antarctic and Arctic populations characterized by a promptly inducible *hsp-70* gene

1
2
3
4 activity [10]. A strengthening of this activity, and presumably of other genes encoding anti-oxidant
5
6 enzymes, would thus well explain the *E. nobilii* unusual capacity to rapidly repair UV-induced
7
8 damage.
