Abstract

It is well-known that the maximum traffic flow that a roundabout entry is able to accommodate depends on the amount of flow circulating in the roundabout carriageway that conflicts with the entry flow exiting from it and strictly related to the geometric characteristics of the roundabout. International guidelines deal with various capacity models requiring different input data and often lead to different results for the same roundabout entry. Recently, an exponential model has been developed for capacity estimates of multi-lane roundabout entries under different conditions of circulating flow and geometrical factors. Such a model was validated by Al-Madani and Saad on data gathered from a sample of existing large roundabouts in Bahrain. Calculations made, applying the developed model, or Bahr model, showed a reasonable fitting to computational data obtained from different international models, as German, French SETRA, American HCM, and so on.

In this paper, we have collected traffic data during peaks or congested periods and measured geometry parameters on twelve large roundabouts located in Tuscany, Italy. The main goal was with a view to testing if the Bahr model could be well suited or not to Italian context. The same previous methodology applied for the Bahr model was followed and found a new exponential entry capacity model, called Tusc. Statistical tests are performed and the paper ends with some comments about the obtained results.

Keywords: roundabout capacity, linear regression and exponential entry capacity models, statistical significance.

1 Introduction

During the Sixties, soon after the United Kingdom and following many other Commonwealth countries, all the traffic circles in Bahrain were converted into modern roundabouts adopting the priority-to-the-circle rule. Since about thirty years after the modern roundabouts began to appear also in Italy.

Nowadays, modern roundabouts are widely spreading all over the world because of their advantages over other types of intersection control. The main reasons are linked to increasing of safety over other cross roads [2] due to a reduction in severity of crashes, and deep improvement of performance, as observed in Europe and the USA after adopting a roundabout in replacement to any other existing type of intersection [3].

At the same time, many countries have developed design guidelines referring to specific models for the capacity evaluation of modern roundabouts. All the capacity models can be classified into two groups. The first one is related to theoretical models based on the gap acceptance theory, with no actual observations. The second group collects empirical regression models, derived on the basis of large samples both of actual observed geometric characteristics and surveyed data of traffic flow parameters. This way, the designer often might fall into a dilemma. On one side there are the theoretical models supporters, as Fisk [4], asserting that regression models are not suited for frequent application due to their large number of data requirements. On the opposite side it is said, as Kimber [5] does, that capacity estimates based on gap acceptance models are not suitable for application in original nationwide contexts due to the amount of factors related to local driver' behaviour and habits.

Two years ago Al-Madani and Saad [1] developed an exponential model for capacity estimate of roundabouts with triple circulating lanes. The model was derived in respect to the entry capacity values obtained from a selected set of international models applied to actual data observed on thirteen large roundabouts in Bahrain.

This paper deals with a first attempt of following the same methodological steps in order to develop an original model on data now gathered from a sample of roundabouts located Tuscany (Italy). Finally, the previous and the present developed models, said BAHR model and TUSC model respectively, were compared through goodness of fit and statistical test procedures in order to state if they can be or not considered the same one.

2 Capacity models

This section is referred to six of popular models related to the capacity of roundabouts and widely used from some decades in Western Europe and Australia, and more recently in US also. All they are suitable to predict the entry capacity as many for a single lane entry as for multi-lane entries. The capacity of the entire roundabout is not considered, as it depends on too many terms. The yield line is the relevant point for capacity analysis, and the approach capacity is the capacity provided at the yield line [6].

The maximum flow rate that can be accommodated at a roundabout entry depends on three factors: the circulating flow on the circulating roadway that conflicts with the entry flow, the exiting flow on the same leg of the entry, and the geometric dimensions and characteristics of the roundabout. When analyzing roundabout legs with more than one entry lane, the capacity for each lane is different, with the dominant stream having the greater capacity. Doubling the number of entry lanes does not give double the total entry capacity. The performance of multiple lane roundabouts will be improved if the inscribed diameter is increased, and if the average entry lane width is increased [7]. This is because the drivers' gap acceptance parameters are reduced. Therefore, driver behaviour is expected to be different at higher circulating flows where priority sharing occurs. A number of fundamental methods applicable to two-way-stop-controlled and two-way-yield-controlled intersection capacity analysis serve as a foundation for roundabout operational performance.

Two different methodological approaches have been used to develop such models: gap acceptance theory and empirical regression. In a gap acceptance model, the driver on the minor (entering) stream is required to select an acceptable gap on the major (circulating) stream, to perform the desired manoeuvre. The "gap" is defined as the headway maintained between two consecutive vehicles in the conflicting stream. In order to cope with particular concerns related to gap acceptance in a roundabout environment, Troutbeck and Kako have developed a theory for incorporating a "limited priority" process, in which the major stream vehicle slows down to allow the minor street vehicle to enter the circulating stream [8]. Linear or exponential empirical regression models are based on traffic volumes at one-minute intervals observed during periods of overflow. A well-suited regression equation, usually linear or exponential, is then fitted to the sample data. Variation in the data is often generated by driver behaviour and geometric design. The influence of geometric design is also included into the model using a multivariate regression equation [7]. The international technical literature quotes several both of theoretical and empirical capacity models, often drawn from national guidelines of various countries. Moreover, some models are complicated requiring extensive input data and tedious calculations as Great Britain RODEL, Australians aaSIDRA and NAASRA, others are far more simple and require few input data as German HBS and US Highway Capacity Manual models.

Capacities estimated in respect to the same instance through these models may widely differ from one model to another. The crucial question of how good the capacity estimate of each model is, calls for further investigations, but it is not the goal of this paper.

2.1 French GIRABASE model

The model is an exponential regression that takes into account a number of geometric parameters and the influence of exiting flow. It is incorporated into a software implementation known as GIRABASE [9] and its form is as follows:

$$C_e = A \cdot \exp(-B \cdot q_g) \quad (1)$$

where:

C_e = maximum entry flow (pcu/h); $q_g = q_a \cdot k_a \cdot (1 - (q_a / (q_c + q_a))) + q_{ci} \cdot k_{t,i} + q_{ce} \cdot k_{t,e}$; q_{ci} = conflicting flow on inner lane (default $0.4q_c$); q_{ce} = conflicting flow on outer lane (default $0.6q_c$); q_a = exiting flow (pcu/h); $A = 3600/t_f (L_e/3.5)$; t_f = follow-up headway = 2.05 s; $B = 3.525$ for urban area (3.625 for rural area); R = radius of the central island (m); L_a = circulating roadway width (m); L_e = entry width (m); L_i = width of the splitter island (m); $L_{i,max} = 4.55 \sqrt{R + (L_a/2)}$; for $L_i < L_{i,max}$ $K_a = (R / (R + L_a)) - (L_i / L_{i,max})$; else $K_a = 0$; $k_{t,i} = \min\{160 / (L_a \cdot (R + L_a)); 1\}$; $k_{t,e} = \min\{1 - ((L_a - 8) / L_a) \cdot (R / (R + L_a)^2); 1\}$

2.2 Great Britain model

The model suggested by Kimber [10] is received into UK guidelines. It is a statistically derived empirical linear formula based on a large number of measurements of capacity at saturated roundabouts.

This method has been incorporated into a software packages widely known as RODEL and ARCADY. The model involves circulating flows and extensive geometric requirements (see also Figure 1), and it has the following form:

$$C_e = F - f_c Q_c \tag{2}$$

where:

$F = 303kx$; $f_c = 0.210kT(1+0.2x)$; $x = v + (e - v)/(1 + 2S)$; $T = 1 + 0.5/(1 + M)$
 $k = 1 - 0.00347(\phi - 30) - 0.978[(1/r) - 0.05]$; $M = \exp[(D - 60)/10]$; $S = 1.6(e - v)/L'$

The geometric parametrs are: e = entry width (m); v = approach half-width (m); L' = effective flare length (m); r = entry radius (m); S = measure of the degree of the flaring; ϕ = entry angle ($^\circ$); D = inscribed circle diameter (m). The predictive equation for entry capacity C_e is given by equation (3) when the product $f_c Q_c$ is a value less than or equal to F ; otherwise $C_e = 0$.

Figure 1: Definition of the geometric requirements in Kimber's equation.

2.3 German HBS model

In 2001, the Brilon-Wu capacity equation has been introduced into the German handbook of highways design and practice, or HBS [11]. This model is an exponential equation relating entry capacity C_e to circulating flow q_c , the number n_e of lanes in the entry, the number n_c of conflicting lanes (1 or 2 with $n_c \leq n_e$) critical gap t_c and follow-up headway t_f and minimum headway Δ of circulating stream:

$$C_e = \frac{n_e^{n_F/(n_F+1)}}{t_f} \cdot \left(1 - \frac{\Delta \cdot q_c}{n_c}\right)^{n_c} \cdot \exp\left[-q_c \cdot \left(t_c - \frac{t_f}{2} - \Delta\right)\right] \quad (3)$$

where: n_F = short lane length = 1.4 vehicles; t_c = 3.3 s, t_f = 3.1 s and Δ = 1.8 s are the suggested default values.

2.4 Australian aaSIDRA

The more recent capacity expressions published in Australia belong to the studies carried out by Akçelik et al. [12] and have been incorporated into the software known as aaSIDRA.

Capacity C_e means the maximum entry flow for an entry lane and it is calculated lane-by-lane as follows:

$$\begin{cases} C_e = \max\{f_{od}q_g; q_m\} \\ q_g = [(1 - \Delta_c q_c)/\beta] + 0.5\beta\varphi_c q_c \exp[-\lambda(\alpha - \Delta_c)] \\ q_m = \min\{q_e; n_m\} \\ f_{od} = 1 - f_{qc}(P_{qd}P_{cd}) \end{cases} \quad (4)$$

where:

$q_c = q_{cr} + q_{co}$ = inner and outer conflicting flow (veh/s); q_e = entry arrival flow (veh/s); $P_{qd}P_{cd} = 0.6$; n_m = minimum entry flow (veh/s); n_c = number of lanes in conflicting flow; Δ_c = minimum headway in circulating traffic (s): $\Delta_c = 2.0$ for $n_c = 1$, $\Delta_c = 1.2$ for $n_c = 2$; λ = arrival headway distribution factor (veh/s): for $q_c \leq (0.98/\Delta_c)$ then $\lambda = (\varphi_c q_c)/(1 - \Delta_c q_c)$, else $\lambda = (49\varphi_c/\Delta_c)$; for $n_c = 1$ $\varphi_c = \exp(-5.0q_c)$, for $n_c = 2$ or 3 $\varphi_c = \exp(-3.0q_c)$; β = follow-up headway.

For the dominant entry lane (lane at a multi-lane with the largest entry flow q_d): $\beta = \beta_d = (\beta'_o - 3.94 \cdot 10^{-4} q_c)$, subject to $1.2 \leq \beta'_d \leq 4$

$\beta'_o = 3.37 - 0.0208D_i + 0.889 \cdot 10^{-4} D_i^2 - 0.395n_e + 0.388 n_c$, subject to $20 \leq D_i \leq 80$ where: D_i = inscribed circle diameter (m); n_e = number of entry lanes.

For the subdominant entry lane (i.e. lane at a multi-lane with the smallest entry flow q_s): $\beta = \beta_s = 2.149 + r_{ds}(0.5135 \beta_d - 0.8735)$, subject to $\beta_d \leq \beta_s \leq 4$ where: $r_{ds} = q_d/q_s$ = ratio of dominant and subdominant flow in the entry; α = critical headway (s): for $q_c \leq 1200$ then $\alpha = 3.6135 - 3.137 \cdot 10^{-4} q_c - 0.339w - 0.2775n_c$, else $\alpha = \beta(3.2371 - 0.339w - 0.2775n_c)$, subject to $3.0 \geq \alpha/\beta \geq 1$ and $2.2 \leq \alpha \leq 8.0$;

w = average entry width (m); if $n_c = 1$ then: $f_{qc} = 0.04 + 0.00015q_c$ for $q_c < 600$, $f_{qc} = 0.0007q_c - 0.29$ for $600 \leq q_c \leq 1200$, $f_{qc} = 0.55$ for $q_c > 1200$; if $n_c = 2$ then: $f_{qc} = 0.04 + 0.00015q_c$ for $q_c < 600$, $f_{qc} = 0.0035q_c - 0.29$ for $600 \leq q_c \leq 1800$, $f_{qc} = 0.55$ for $q_c > 1800$.

2.5 Australian NAASRA

The National Association of Australian State Road Authorities, or NAASRA, adopted Tanner's method for delays and capacity of uncontrolled intersections both in the 1979 guidelines to urban intersection design and updated 1982 roundabout guidelines. The model is summarized as follows:

$$C_e = n_c q_c \frac{\exp(-q_c t_c)}{1 - \exp(-q_c t_f)} \quad (5)$$

where: q_c = circulating flow; n_c = number of conflicting lanes; t_c = critical interval = 6 s; t_f = follow-up time = 3 s.

2.6 United states HCM2000

After the first introduction in 1997, the 2000 edition of Highway Capacity Manual [13] refers to a method for multi-lane roundabout capacity as described below:

$$C_e = 1230 \cdot n_c \cdot \exp(-0.0009q_c) \quad (6)$$

where, as above: q_c = circulating flow; n_c = number of conflicting lanes.

3 Methodology

Following the methodology suggested by Al-Madani and Saad [1] in their previous work, an original capacity model has been developed on geometric and traffic data observed in twelve large roundabouts located Tuscany (Italy). We named this model TUSC in order of distinguishing from the one developed in Bahrain, and referred as BHR model in the following. Then, the TUSC model is in its turn an equation linking roundabout entry capacity to the corresponding circulating flow. Sample data were collected during rush hours and under saturation flow conditions. Some different types of models were developed firstly using a least square regression procedure. Secondly, all the resulting linear, logarithmic, polynomial, power and exponential equations were evaluated for best experimental data fitting. Finally, capacities of the twelve Italian roundabouts were calculated using both TUSC model and BHR one. The two resulting sets were statistically analyzed in order to determinate if they may be considered to have come from the same population, or, in other words, as to whether using TUSC or BHR model is the same or different in practice. Such hypothesis has been tested by computing of both the differences of means and the homogeneity of variances by the exact F-test.

4 Sample data

Data has been collected on a sample of twelve large roundabout located in the North-Western part of Tuscany, Italy. All over they have the circulating roadway width suited for two lanes operations, while the entries are sometimes with two lanes or one lane only, especially for those sizes falling into the lower range from 40 to 45 metres of inscribed diameter. Traffic flow measurements made during weekday a.m. and p.m. peak hours were related to each single leg. Field traffic data were firstly video recorded by digital camera for about two hours per each selected peak period of interest. Successive analysis of the video recorded images made we able to refer traffic values on the standard 15-minutes basis.

On the other side, geometric parameters were accurately observed recurring to on-field measurements by laser instruments. Few problems of local accessibility were coped with searching for and viewing directly the original building up design layouts from National Highway Agency – ANAS and public road bureaus of local municipalities. Satellite images from Google Earth™ have also helped to refine and/or improve some of details belonging to the geometric sample set.

Table 1 resumes the main distinctive characteristics of the twelve roundabouts sampled in Tuscany (It).

Table 1: Sample composition of the twelve roundabouts observed in Tuscany.

<i>D range (m)</i>	<i>N. of roundabouts</i>	<i>3 legged</i>	<i>4 legged</i>
40 ÷ 45	2	–	2
45 ÷ 53	3	–	3
> 53	7	5	2

5 TUSC model developing

The six models quoted above were applied to the sample data. This way a set of capacity values has been generated and processed by a least square method search for the best goodness of data fitting [14].

The performed analysis leads to five different types of models: linear, logarithmic, exponential, quadratic and power regression. Among them, the exponential model shows the best sample data fit when compared with the other models because it holds the highest R^2 value ($R^2 = 0.504$).

Table 2 shows the R^2 values obtained for each best corresponding model among each one of the five tested forms. It is worthwhile remembering that the model type set up in Bahrain, the said BHR model, is also exponential as below:

$$C_e = 2768.0 \cdot \exp(-0.0007q_c) \quad (7)$$

While the selected best fit equation for the TUSC model is:

$$C_e = 2272.2 \cdot \exp(-0.0009q_c) \quad (8)$$

At the first look, equations (7) and (8) are quite similar. Therefore, it is moved up along this resemblance that the two models were submitted to a test analysis concerning their differences, as referred in the following section.

Table 2: Best fit capacity equations for each one of five model forms obtained in respect to the sample data observed in Tuscany (It.).

Model form	Best fit equation	R ²
Linear	$C_e = 2132.6 - 1.112q_c$	0.426
Logarithmic	$C_e = 3556.9 - 336.4 \cdot \ln(q_c)$	0.294
Exponential	$C_e = 2272.2 \cdot \exp(-0.0009q_c)$	0.504
Quadratic	$C_e = 2190.8 - 1.3604 q_c + 0.0002(q_c)^2$	0.428
Power	$C_e = 6194.9 q_c^{(-246)}$	0.291

6 Experimental comparisons

The results depicted in Figure 2 clearly show that the TUSC model highly underestimates the entry capacity for given circulating flow and corresponding geometric characteristics when compared with those estimated from GIRABASE. The comparison to RODEL and aaSIDRA models is more jumping and shows a high dependency by single values pairing of the entry geometry and its own circulating flow. On the contrary, the estimated entry capacities by TUSC appears generally overestimated when the German HBS method is

Figure 2: Developed capacity model for Italian large roundabouts, or TUSC model, along with the points generated by other six international models to the twelve roundabouts selected in Tuscany (It).

considered. It is also interesting to draw attention to the fact that in correspondence of very high values of circulating flows either all the considered international models and, of course, the derived one lead to a lower spreading of the results. Therefore, during traffic peaks the more complicated models, such as the UK RODEL the Australian aaSIDRA that are requiring as many geometric parameters as a number of boring equations, did not show better capacity estimates than much simpler ones.

This fact has been observed previously [1] and it might be related to the drivers' behavior in approaching and crossing roundabouts at relatively low speeds during any congested period. These traffic conditions produce a very limited influence upon geometry, such as entry angle, flare length and entry radius, simply because the motorists have limited space for maneuvering and a corresponding lowered road space perception. Geometry is more influencing to the drivers during off-peaks, when they are actually forced to slow down the approaching and crossing speeds through well designed roundabout geometric features.

6.1 TUSC versus BAHR

The exponential equation set up in Bahrain, or BAHR model, has been applied to the twelve roundabouts sample data. The obtained entry capacity values are depicted in Figure 3 jointly with the ones derived through the previous models. Figure 3 shows also the two curves generated by TUSC equation (7) and BAHR equation (8), respectively.

Figure 3: BAHR capacity model and TUSC model along with the sample values generated by GIRABASE, HBS, RODEL, HCM aaSIDRA and NAASRA models to the twelve roundabouts selected in Tuscany (It).

On one side, the TUSC equation leads to values quite resembling to capacities obtained by the Australian NAASRA model, especially for instances with two-lanes entry and circulating flows less than 500 veh/h. On the opposite side, the BAHM model shows its major closeness to the sample estimates given by French GIRABASE when circulating flows are in the range from 300 veh/h to 1100 veh/h.

Nevertheless, one doesn't forget that the two models are obtained in respect of two fairly different sample compositions, as it is displayed in Table 3. Wide variations in capacity estimates between the two highlighted models when applied to the same measurements gathered in Tuscany, have suggested testing for their statistical significance of differences.

Table 3: Ranges of the geometric parameters measured in the sampled roundabouts in Bahrain and in Tuscany.

<i>Parameter</i>	<i>Bahrain</i>	<i>Tuscany</i>
Number of circulating lanes	2 or 3	2
Number of entry lanes	2 or 3	1 or 2
Inscribed diameter (m)	63 ÷ 150	42 ÷ 59
Entry angle	8 ÷ 32.5	4 ÷ 45
Entry radius from edge (m)	11.5 ÷ 120	13 ÷ 70
Flare effective length (m)	10 ÷ 55	9 ÷ 100
Entry width all lanes (m)	6.5 ÷ 16	4 ÷ 8
Radius of central island (m)	24 ÷ 64.5	11.8 ÷ 21.5
Width of splitter island (m)	18 ÷ 82	5 ÷ 27.8

The differences between the estimates of the two pairs constitute the sample data upon which the hypothesis of homogeneity is to be based. The homogeneity of variances is tested by computing the so called “ F ” ratio, as follows:

$$F = \frac{s_T^2}{s_B^2} \quad (9)$$

where s_T^2 is the larger variance and s_B^2 is the smaller one.

The computed value of F is then compared with the critical value, F_{crit} , obtained from a specific table having the desired α level of significance (usually $\alpha = 0.05$) and entered in correspondence with each variance degrees of freedom, or $d.f.$ [15]. If the computed (test) F value is less than F_{crit} , then variances are accepted as homogeneous, and the hypothesis that the two populations are equals is adopted.

Therefore, the F ratio has been computed in respect to the two capacity estimates sample pairs, one generated by the TUSC equation (7) and the other one by the BAHM equation (8) when applied to the data set related to the twelve roundabouts observed in Tuscany. The foregoing analysis of such comparison is summarized in Table 4.

Table 4: Results of the F ratio test made upon the two sample pairs generated by TUSC and BAHR equations for twelve roundabouts in Tuscany.

<i>Item</i>	<i>value</i>
TUSC sample mean	1478.11
BAHR sample mean	2098.84
TUSC sample variance	177613.65
BAHR sample variance	227872.45
Variance <i>d.f.</i>	43
α level of significance	0.05
F ratio	1.28
F_{crit}	1.66
Null hypothesis $H_0: s_T^2 = s_B^2$	accepted

Table 4 brings into prominence the ultimate fact: since the sample F ratio is larger than the 0.05 level of significance tabular value $F_{crit} = F_{0.05,43,43}$, given in the row of 43 *d.f.* and the column of 43 *d.f.*, the null hypothesis H_0 is accepted. So, it can be assumed that the variances came from equal populations; that is, the variances are homogeneous.

Now, the differences of population means can be tested by the Behrens-Fisher method which formulates the following hypothesis:

$$|\bar{X}_T - \bar{X}_B| < t_{\alpha,\nu} \sqrt{\frac{s_T^2}{n_T} + \frac{s_B^2}{n_B}} \quad (10)$$

where: $t_{\alpha,\nu}$ = (tabular) value of t -Student for the significance level α and degree of freedom $\nu = (n_T + n_B - 2)$.

From the data of Table (4) the inequality (10) we obtained $|1478.11 - 2098.84| = 619.73$ and in respect to $\nu = 82$ and $t_{0.05,82} = 1.99$; restating the hypothesis: $619.73 < 1.99 \times 96 = 191.04$ which is false.

Therefore, it must be concluded the hypothesis that the means represented by the two samples to be equal is false with 95% level of confidence, i.e. $(1 - \alpha)$. When either the F test or the test of means fails due to slow lack of equality, the hypothesis that populations are equal is rejected. Thus, the samples may be considered to have come from different populations. In other words, the entry capacities given by the TUSC model are not equal to the entry capacities estimated the BAHR model in respect to the same roundabout.

6.2 TUSC Model vs. field data from Bahrain

The TUSC model for entry capacity estimation was fit to the field data for several roundabouts with 2 entry and circulating lanes in Bahrain. As can be seen from Table 5, clear difference, of around 26%, exist between the TUSC and the field data. However, the standard error of the mean of the actual field data is

slightly higher than that for the modelled data. The paired t-test result also showed significant difference between the two (Table 6). The higher capacity results for Bahrain, when compared with TUSC, might be due to the clear differences in the geometric characteristics of the considered roundabouts and to the drivers' average headway requirements for entries. The latter is not measured here and requires further analysis. However, one may note that the average inscribed diameter for the roundabouts utilized in TUSC is around 40 to 53 m (see Table 1) while that in Bahrain is in the range from 63 to 150 m. As been mentioned earlier, higher diameters might lead to better capacities up to certain limits. Comparison of headways is not considered here since it is not within the scope of the work studied here. However, it is interesting to have an experimental comparison between TUSC (i.e. Italy) and Bahrain.

Table 5: Comparison between TUSC modelled data and Bahrain field data.

<i>Parameter</i>	<i>mean</i>	<i>St. dev.</i>	<i>St. error of mean</i>	<i>sample</i>
Bahrain Field Data	1014.9	513.7	83.3	38
TUSC modelled data	748.2	402.6	65.3	38

Table 6: Paired t-test of TUSC modelled results vs. Bahrain field data.

<i>Parameter</i>	<i>mean difference</i>	<i>St. dev.</i>	<i>St. error of mean</i>	<i>d.f.</i>	<i>t-test</i>	<i>significance (2-tailed)</i>
Bahrain field – TUSC modeled	266.7	599.4	97.2	37	2.74	0.009

7 Conclusions

An empirical attempt of deriving a roundabout capacity model has been made following the methodology firstly suggested and applied in Bahrain but now based on data gathered in Tuscany. This way, the original exponential model TUSC has been developed. The hypothesis of equality between the two models at hand has been tested by considering differences between the two pairs of sampled estimates given either by TUSC and BHR models. The test fails due to the lackness of equality of means and the two models results strongly linked to their respective data base original requirements.

Nevertheless, the present research effort should be put forward enlarging the sample sets by gathering more field observations, both in Bahrain and in Italian roundabouts.
