18 **Abstract**

19 Bubble growth strongly affects the physical properties of degassing magmas and their

20 eruption dynamics. Natural samples and products from quench experiments provide

21 only a snapshot of the final state of volatile exsolution, leaving the processes

22 occurring during its early stages unconstrained. In order to fill this gap, we present *in-*

23 *situ* high-temperature observations of bubble growth in magmas of different

24 compositions (basalt, andesite and rhyodacite) at 1100 to 1240 °C and 0.1 MPa (1

25 bar), obtained using a moissanite cell apparatus. The data show that nucleation occurs

26 at very small degrees of supersaturaturation (<60 MPa in basalt and andesite, 200

27 MPa in rhyodacite), probably due to heterogeneous nucleation of bubbles occurring

28 simultaneously with the nucleation of crystals. During the early stages of exsolution,

29 melt degassing is the driving mechanism of bubble growth, with coalescence

30 becoming increasingly important as exsolution progresses. Ostwald ripening occurs

31 only at the end of the process and only in basaltic melt. The average bubble growth

32 rate (G_R) ranges from $3.4*10^{-6}$ to $5.2*10^{-7}$ mm/s, with basalt and andesite showing

33 faster growth rates than rhyodacite. The bubble number density (N_B) at nucleation

34 ranges from $7.9*10^4$ mm^{-3} to $1.8*10^5$ mm^{-3} and decreases exponentially over time.

35 While the rhyodacite melt maintained a well-sorted bubble-size distribution (BSD)

36 through time, the BSD´s of basalt and andesite are much more inhomogeneous. Our

37 experimental observations demonstrate that bubble growth cannot be ascribed to a

38 single mechanism but is rather a combination of many processes, which depend on the

39 physical properties of the melt. Depending on coalescence rate, annealing of bubbles

40 following a single nucleation event can produce complex bubble size distributions. In

41 natural samples, such BSD´s may be misinterpreted as resulting from several separate

42 nucleation events. Incipient crystallization upon cooling of a magma may allow

43 bubble nucleation already at very small degrees of supersaturation and could therefore

44 be an important trigger for volatile release and explosive eruptions.

1. Introduction

Explosive volcanic eruptions are powered by volatiles exsolving from magmas during their ascent toward Earth's surface. At constant temperature, the solubility of volatile species (mostly H_2O and CO_2) is controlled by pressure and melt composition (Moore et al. 1998; Papale 1999; Liu et al. 2005; Ni and Keppler 2013). The combination of these two parameters determines the depth at which volatiles exsolve from the melt. The expansion of the resulting gaseous phase (i.e., bubbles) controls the effusive or explosive behaviour of magmas during volcanic eruptions. The eruptive style is thus determined by the mechanisms of bubble nucleation and growth (i.e., melt degassing, bubble coalescence, Ostwald ripening), which can be inferred only through bubble size distribution analysis of volcanic rocks or experimental products (e.g., Proussevitch et al. 2007; Shea et al. 2010; Lautze et al. 2011). Unlike crystal phases, the molar volume of the gas phase forming bubbles is much higher than that of the melt, therefore bubbles cannot be treated like crystals in size distribution studies (Proussevitch et al. 2007). Moreover, the higher mobility of the gas phase in the melt as compared to that of crystals implies another limitation for the textural interpretation of volcanic rocks, which only record the last frame of the degassing process. Given these restrictions, experiments with analogue materials have been performed and experimental products have been compared to natural textures (Blower et al. 2002). However, such comparisons rely on scaling assumptions to account for differences in thermal and chemical conditions. These assumptions may not always be valid. For this reason, accurate insights into the exsolution process can be obtained only through direct observations at conditions comparable to those of degassing magmas.

First *in-situ* observations of bubble growth were obtained heating hydrous glassy sample at ambient pressure in heating stages (Bagdassarov et al. 1996; Navon et al. 1998; Liu and Zhang 2000). These studies investigated bubble growth in rhyolitic melts and showed experimental results consistent with the growth laws inferred by theoretical models (Toramaru 1989; Toramaru 1995; Proussevitch et al. 1993; Lyakhovsky et al. 1996). More recently, high-pressure devices were developed and used to investigate *in-situ* bubble growth in silicic melts (Martel and Bureau 2001; Gondé et al. 2006; Gondé et al. 2011). The experimental results were also consistent with observations of natural products, demonstrating the reliability of the experimental approach to the problem of magma vesiculation.

86   The low experimental temperature (generally well below 1000 °C) and the

87 exclusive use of rhyolitic-type melt compositions are the main limitations of the

88 experiments carried out so far. To overcome these limitations and to advance the

89 investigation of bubble growth to higher temperatures and to basaltic compositions,

90 we present new experimental *in-situ* observations of vesiculation obtained on basalt,

91 andesite and rhyodacite melt compositions at temperature up to 1240 °C, using a

92 recently developed moissanite cell apparatus (Schiavi et al. 2010). This technique was

93 used by Schiavi et al. (2009) to observe the crystallization of a basaltic andesite and it

94 can also be applied to investigate the kinetics of volatile exsolution in magmas. With

95 some improvements of the initial experimental design, we have studied synthetic

96 melts of different composition (basalt, andesite and rhyodacite) to unravel the

97 dynamics of bubble growth in magmas at its early stages.

98

99

100 **2. Experimental and analytical methods**

101

102   *2.1 Sample preparation and characterization*

103   We used synthetic glasses as starting material representative for different

104 magma compositions (basalt, andesite and rhyodacite), obtained by melting a mixture

105 of analytical grade oxides, carbonates and nitrates at 1 atm and 1600 °C for two hours

106 in a platinum crucible. After this, basalt and andesite were melted once again under

107 vacuum (P=10^{-2} mbar) at 1500 °C for 4 hours. Resulting glasses were clear and

108 bubble-free, as confirmed with a scanning electron microscope (SEM), see Figure A1

109 in the electronic appendix. Chemical analyses of these glasses were obtained with a

110 JEOL JXA-8200 electron microprobe, using a 10 μm defocused beam, accelerating

111 voltage of 15 kV and current of 15 nA (Table 1). To improve the optical transparency

112 of the sample, in the basalt and andesite compositions, all FeO was replaced by MnO.

113   Despite the melting of the starting mixture at atmospheric pressure (rhyodacite)

114 or under vacuum (basalt and andesite), the resulting glasses contained small

115 concentrations of dissolved water (as OH⁻) and CO_2 (as carbonate, CO_3^{2-}). Volatile

116 contents in the glasses were measured on 200-1800 μm thick, double polished

117 samples, using a Bruker IFS 120 Fourier transformed infrared (FTIR) spectrometer

118 coupled to an infrared microscope. A narrow-band MCT detector was used together

119 with a tungsten source and a Si-coated CaF_2 beam splitter to measure the 3600 cm^{-1}

120 band of OH^-, while the same detector was used together with a globar source and a

121 Ge-coated KBr beam splitter to measure the carbonate peak at ca. 1550 cm^{-1}. Water

122 and CO_2 contents were calculated using the molar absorption coefficients reported by

123 Yamashita et al. (1997) and by Ni and Keppler (2013). Results are reported in Table

124 1, together with the volume that H_2O and CO_2 would occupy if they were entirely

125 exsolved.

126

127   *2.2 Moissanite cell experiments*

128   The moissanite cell assembly resembles a Bassett-type externally heated

129 diamond anvil cell, with diamond anvils replaced by large moissanite windows (a

130 detailed description is given by Schiavi et al. 2010). A sample (glass disk of ca. 1.8

131 mm diameter) was sandwiched between two moissanite windows and surrounded by a

132 yttrium-doped ZrO_2 gasket. Two or three concentric coils of Pt_{90}-Rh_{10} wires on

133 pyrophyllite substrates around each window were used for heating (Figure A2). A

134 digital camera placed on a transmission optical microscope (Zeiss Axioscope 40;

135 output to either eyepieces or camera-computer) recorded time-lapse pictures and

136 movies of the sample. Samples from the starting glasses were prepared in 50-100 μm

137 thick, doubly polished disks that were fitted into the gasket and sandwiched between

138 the moissanite windows.

139   Before heating the sample to *super-liquidus* temperatures (1240 °C basalt, 1200

140 °C andesite, 1100 °C rhyodacite), the temperature inside the cell was held for a few

141 hours at 650 °C (experiments with rhyodacite) or 800 °C (experiments with basalt and

142 andesite) in order to release strain on the cell and to minimize the deformation of the

143 cell during heating. No pressure was applied to the sample. The temperature was then

144 increased with a rate of 167 °C/min and held constant at 1240 °C for the basalt melt,

145 at 1200 °C for the andesite melt and at 1100 °C for the rhyodacite melt during the

146 entire exsolution process. These temperatures are 10 to 50 °C above the *liquidus*

147 temperature calculated for these melt compositions using MELTS (Ghiorso and Sack

148 1995). The experiments were terminated after 0.5-7 hours and temperature was

149 rapidly decreased with cooling rates varying from 50 to 100 °C/min. During all the

150 experiment, Ar was flushed through the cell.

151   Image analysis of bubbles was carried out using the free WEB software package

152 ImageJ (Image Processing and Analysis in Java; http://rsb.info.nih.gov/ij/).

153 Microscope pictures were converted to binary (8 bit) images. To limit the error on

154 particle counting and measuring, the touching edges of adjacent bubbles were drawn

155 manually. Bubble growth rate (G_R) was calculated in each picture by the average

156 increase of bubble radius over time elapsed since the final run temperature had been

157 reached. The bubble number density (N_B) was calculated in selected pictures from

158 each experiment, using the following equation (Gardner 2007):

159
$$N_B = \frac{\phi_M}{\sum\left(\left(\frac{n_i}{N_T}\right)V_i\right)} \qquad (1)$$

160 where n_i and V_i are the number and volume of bubbles of diameter i, respectively, N_T

161 is the total number of bubbles and ϕ_M is the porosity, which is calculated as the

162 volume fraction of bubbles in the sample (Gardner et al. 1999):

163
$$\phi_M = \frac{V_{bubble}}{V_{bubble} + V_{melt}} \qquad (2)$$

164

165

166 **3. Results**

167

168 *3.1 Bubble nucleation and growth mechanisms*

169 Bubble nucleation occurred in all experiments during heating, beyond the glass

170 transformation temperature, but before reaching the *liquidus* temperature. During

171 melting, all samples became nearly opaque, because of the sudden formation of

172 bubbles and crystal nuclei (Figure 1 a-c). The clarity of images improved significantly

173 a few seconds after the achievement of the set point temperature at t_0, revealing the

174 existence of small bubbles (1-4 μm). During the last stage of the heating process,

175 thermal dilatation of the glassy disks caused a slight deformation of the bubbles at the

176 edge of the sample. This was clearly observed in the experiments performed with the

177 more viscous rhyodacitic melt (Figure 1 d-e; see also video in the electronic

178 appendix). Immediately after relaxation of the melt, bubbles formed in the basalt were

179 slightly larger than those in andesite, and consistently larger than those in rhyodacite

180 (Figure 2).

181 The opacity of the sample during melting prevented the evaluation of possible

182 effects of the moissanite surface on bubble nucleation. Apparently, bubbles nucleated

183 homogeneously in the sample, since most of the experiments showed small bubbles

184 distributed throughout the thickness of sample and spread all over its area. The

185   movement of bubbles during the thermal dilatation of the sample also suggests that

186   bubble nucleated in the melt, rather than at the interface with the moissanite. In some

187   experiments with basalt, a decrease of the bubble number density was observed

188   toward the rim of the glassy sample, possibly because some degassing occurred

189   through the outer surface of the sample.

190   Bubble nucleation occurred exclusively at the beginning of each experiment and

191   was then followed by bubble growth. After relaxation, bubble growth continued

192   without deformation until the bubble achieved a critical diameter, corresponding to

193   the thickness of the glassy disks. At this point, because bubble deformation became

194   significant and menisci formed on the moissanite windows, the experiments were

195   either terminated or the images captured later were not analysed. In terms of bubble

196   growth dynamics, all the experiments showed consistent results independent from the

197   composition of the melt, with melt degassing and coalescence being the prevailing

198   mechanisms of bubble growth. Growth by melt degassing dominated during the very

199   early stages of the experiments whereas bubble coalescence became increasingly

200   important after bubbles had grown enough to interact with each other. The overall

201   increase of porosity over time suggests that exsolution continued throughout the

202   experiments, despite occurring faster at the very beginning of the experiment and

203   eventually decreasing with time. Importantly, none of the experiments considered in

204   this study showed bubbles moving within the melt, which would have favored

205   coalescence. Indeed, thinning and disruption of melt septa between bubbles was the

206   prevailing mechanism of bubble coalescence (Castro et al. 2012). Immediately after

207   the coalescence of two bubbles, the relaxation of the newly formed bubble occurred

208   slightly faster in basalt and andesite than in rhyodacite, but within a few seconds

209   spherical shape was restored (Figure 3; see video in electronic appendix). Coalescence

210   induced an appreciable increase of diameter of the newly formed bubble, with a factor

211   between 1.2 and 1.5, depending on the initial size of the bubbles.

212   Ostwald ripening occurred towards the end of the experiments (at low values of

213   bubble number density) and only in some experiments performed with basalt. The

214   effect of Ostwald ripening was minor compared to that of coalescence, because it

215   required the presence of bubbles of different size (the distribution in rhyodacite was

216   basically unimodal; Figure 2), with very small bubbles (<10 μm) close to larger ones

217   (>50 μm). These smaller bubbles dissolved in the melt feeding the closest bubbles

218   without producing an appreciable increase in size, as observed during coalescence
219   (Figure 4).
220

221   *3.2 Bubble growth rate (G_R) and bubble number density (N_B)*

222   We already pointed out that bubbles that formed in the basaltic melt at the
223   beginning of the experiment were slightly larger than those in andesite, and
224   consistently larger than those in rhyodacite. This reflects the difference of growth
225   rates in melts of different composition. According to our experiments, bubble growth
226   follows a linear law ($r = G_R*t + c$), with a slope that progressively decreases from
227   basalt to rhyodacite (Figure 5 a). Bubble growth rates (G_R), which are given by the
228   slope of the linear fit, are therefore $3.4*10^{-6}$ mm/s, $1.8*10^{-6}$ mm/s and $5.2*10^{-7}$, for
229   basalt, andesite and rhyodacite, respectively (Table 2). The linear law closely
230   describes bubble growth for t>20 s, but cannot be used to predict bubble size at the
231   very beginning of the exsolution (when the opacity of the sample prevented the clear
232   observation of the process). It is clear, however, that bubble growth at this stage was
233   extremely fast (bubbles of several microns had already formed a few seconds after the
234   achievement of the experimental temperature). Hence, the classical formulation of
235   bubble growth with the bubble radius proportional to the square root of time (Sparks
236   1978; Toramaru 1989; Bottinga and Javoy 1990; Proussevich and Sahagian 1998), or
237   the logarithmic law proposed by Martel and Bureau (2001), may be more adequate in
238   describing bubble growth at the very beginning of exsolution. The contrast between
239   bubble growth at the beginning of the exsolution process and at a later stage implies a
240   significant decrease of G_R shortly after the beginning of exsolution. At t>20 s, G_R
241   remains constant through time (Figure 5 b).

242   The bubble number density (N_B) decreases with time following an exponential
243   function (Table 2; Figure 6 a). The value of N_B at nucleation can be obtained by the
244   intercept of the curves with the zero-time of the experiments, yielding values of
245    $1.8*10^5$ mm^{-3} for rhyodacite, to $9.5*10^4$ mm^{-3} for basalt and $7.9*10^4$ mm^{-3} for
246   andesite. The shifting of the N_B curves can be related to the different rate of bubble
247   coalescence observed in the three melt compositions, with the rhyodacite showing the
248   slowest rate and the highest density of bubbles. By close approximation (assuming a
249   negligible effect of Ostwald ripening), the bubble coalescence rate (C_R) can be
250   expressed as the negative derivative of N_B with respect to time (Figure 6 b):

251
$$C_R = -\frac{dN_B}{dt} \qquad (3)$$

252   Unlike for N_B, the C_R cannot be extrapolated for t<20 s, because at this stage

253   melt degassing is the prevailing mechanism and coalescence is not likely to start

254   before bubbles grew enough to interact with each other.

255

256   *3.3 Bubble size distribution*

257   Bubble size distribution curves are reported in Figure 7 where they are

258   represented by the frequency of bubbles within a specific size class (based on the area

259   of the bubble) and in Figure 8 where they are reported as cumulative distributions of

260   volumetric classes (following the representation of Bai et al. 2008).

261   The faster bubble growth and coalescence rates in basalt and andesite produced

262   less homogeneous bubble size distributions than in rhyodacite. In basalt, bubbles

263   rapidly evolve from a polymodal distribution to a poorly sorted distribution with a

264   positive skew and a mode between 64 and 128 μm^2 (Figure 7 a). In andesite, bubble

265   growth proceeds with a rate similar to that of basalt, but bubbles achieve a bimodal

266   distribution (Figure 7 b). The slowest growth rate produced in rhyodacite the most

267   sorted distribution with a mode shifting through time toward larger bubble sizes and a

268   tail developing toward left (Figure 7 c).

269   Cumulative bubble size distributions show trends comparable with those

270   obtained by X-ray micro-tomography of high-pressure experiments (Bai et al. 2008)

271   and display exponential law relations, independent of melt composition and

272   vesicularity (Figure 8). The exponential law relation closely matches the bubble size

273   distribution of rhyodacite; however, in both basalt and andesite the central segment of

274   the curve rather seems to follow a power law relation, which rotates counterclockwise

275   with time around the volume of 1000 μm^3. This trend is remarkably similar to that

276   observed in crystal size distributions studies and actually reveals a difference in

277   growth rate between the smaller bubbles and the larger ones.

278

279

280   **4. Discussion**

281

282   *4.1 Effect of volatile saturation on bubble nucleation*

283   According to the data in Table 1, the amount of H_2O in our samples (10-20 ppm

284   in basalt and andesite and ca. 400 ppm in rhyodacite) is small compared to the amount

285   of dissolved CO_2 in the melt. The complete exsolution of the H_2O dissolved in each

286   sample alone would be sufficient at 0.1 MPa to produce a gas phase with a volume

287   comparable or greater than the measured volume of bubbles. Most likely, however,

288   CO_2, which is relatively abundant in the melt compared to water, is the main

289   component of the gas phase exsolved during our experiments.

290   The supersaturation pressure (ΔP) is defined as the difference between the

291   saturation pressure of the volatile species dissolved in the melt and the pressure at

292   which bubble nucleation occurs. In our experiments bubbles nucleate at 0.1 MPa and

293   the supersaturation pressure corresponds approximately to the saturation pressure of

294   the CO_2 present in our samples, ignoring the much smaller contribution of water.

295   Based on the interpolation of several CO_2 solubility studies, Ni and Keppler (2013;

296   and references therein) found that CO_2 solubility increases with pressure linearly

297   following a slope 5.67 ppm CO_2/MPa (almost independent of melt composition).

298   Using this relation, we can roughly calculate ΔP values of 18, 51 and 200 MPa for

299   basalt, andesite and rhyodacite, respectively. The values obtained for basalt and

300   andesite are smaller than those reported in previous studies for homogeneous

301   nucleation (e.g., Gondé et al. 2011). Mourtada-Bennefoi and Laporte (2002) found

302   that the degree of supersaturation in rhyolitic magmas increases for decreasing

303   concentration of H_2O and increasing concentration of CO_2. According to these

304   authors, minimum ΔP values (27-94 MPa) are obtained with 630 ppm of CO_2 and 7

305   wt.% H_2O, whereas at reduced water content (4.6 wt.%) and higher CO_2 (800 ppm)

306   ΔP increases over 160 MPa. Therefore, we should expect to observe bubble

307   nucleation in the basalt at ΔP higher than 18 MPa. For rhyodacite, ΔP is about one

308   order of magnitude higher than for basalt, but this value may still be too low to

309   produce homogeneous nucleation in nearly dry melts (ΔP is roughly 150 MPa in

310   water-rich melts; Mourtada-Bennefoi and Laporte 1999; Mangan and Sisson 2000;

311   Mourtada-Bennefoi and Laporte 2004). Indeed, the fact that the rhyodacitic melt (as

312   also the basalt and the andesite) did not degas to equilibrium during melting at 1600

313   °C, suggests that the ΔP was not sufficient for bubble nucleation.

314   The effect of CO_2 concentration on ΔP has never been investigated in detail in

315   water-poor systems and, in most of CO_2-bearing experiments, this effect was probably

316   hidden by the dominant presence of water. Bai et al. (2008) found that no significant

317 effect is observed in basalt at CO_2 concentrations within few hundreds ppm, whereas

318 the effect becomes noticeable at concentration higher than 800 ppm.

319   In the classic theory of bubble nucleation, the ΔP is given by (Hirth et al. 1970;

320 Hurwitz and Navon 1994):

321
$$\Delta P = \sqrt{\frac{16\pi\sigma^3}{3kT\ln\left(\frac{J_0}{J}\right)}} \tag{4}$$

322   where σ is the surface tension, k is the Boltzman constant, T is the temperature,

323 J is the nucleation rate and J_0 is a parameter depending on a number of other

324 parameters characteristic for the volatile species dissolved. According to this

325 equation, the elevated temperatures in our experiments, as compared to many other

326 experiments, could have somehow reduced supersaturation pressure. This effect,

327 however, is expected to be rather small. A more likely explanation for the rapid

328 bubble nucleation and the small supersaturation pressures we observe is that the

329 nucleation occurred during heating shortly before reaching the *liquidus* temperature

330 and may have coincided with the nucleation of crystals, which dissolved again upon

331 further heating (Figure 1). Crystal nuclei may have different atomic arrangements and

332 different surface properties than macroscopic crystals, which could explain why the

333 supersaturation pressures we observe are very small. Our observations are, however,

334 completely consistent with the study of Hurwitz and Navon (1994), who showed that

335 the presence of microlites can reduce supersaturation pressures in hydrous rhyolite

336 melts to values as low as 1 MPa. To demonstrate that bubble nucleation in our

337 experiments was likely related to incipient crystallization, we heated some glass chips

338 of our starting materials in a furnace with the same heating rate as in the moissanite

339 cell experiments, but quenched the sample after the glass transformation temperature

340 had been exceeded. Investigation of these samples showed the nucleation of bubbles

341 on the surface of newly formed crystals (Figure A3 in the electronic appendix).

342   The effect of heterogeneous nucleation may also explain, why bubble

343 nucleation still occurred in experiments with basalt and andesite despite the fact that

344 these samples had been held for 1600 °C in air and in vacuum for several hours. At

345 these *super-liquidus* temperatures, crystal nuclei were not present and heterogeneous

346 nucleation was impossible. Therefore, bubbles could only form by homogeneous

347 nucleation, which requires much higher supersaturation pressures, so that part of the

348 volatiles remained dissolved in the melt. The higher volatile content of the rhyodacite

349 is related to the fact that it was only molten in air, not in vacuum; this imposes higher

350 supersaturation pressures in the subsequent moissanite cell experiments.

351

352   *4.2 Bubble growth and evolution of bubble size distribution*

353   Evaluating the contribution of each bubble growth mechanism from the texture

354 of volcanic rocks is challenging, since the traces of these mechanisms are commonly

355 obliterated during the emplacement of the magma (e.g., deformation and channeling

356 of vesicles during the ascent of the magma in the conduit; Bouvet de Maisonneuve et

357 al. 2009). However, in some cases, bubble size distribution studies can be used to

358 assess the occurrence of certain mechanisms of bubble growth (Shea et al. 2010). *In-*

359 *situ* observations provide valuable insights into the effect of growth mechanisms on

360 bubble size distributions. To overcome the analytical problem of tracking each single

361 growth mechanism (melt degassing, bubble coalescence and Ostwald ripening) and

362 thus, to provide a more direct comparison to natural textures, we have measured the

363 growth of bubbles based on their average size at different times during the

364 experiment.

365   All experiments show a fast bubble growth, prompted by melt degassing shortly

366 after nucleation (<20 s), and a nearly linear growth for the rest of the experiment,

367 dominated by bubble coalescence (Figure 5 a). As result, bubble growth rates

368 decrease rapidly in the first 20 s (by roughly two orders of magnitude), and then they

369 remain nearly constant for the rest of the experiment (Figure 5 b). The fast initial

370 growth is consistent with experimental data by Gondé et al. (2011), who reported a

371 logarithmic growth law in the first 10 s of the experiment, with an average growth rate

372 of $4.5*10^{-4}$ mm/s (i.e., same order of magnitude as we observe for basalt and andesite

373 after 30 and 45 s, respectively; Table 2). Probably due to limitations of the

374 experimental setup, the authors did not report data for time >10 s. However, a

375 prolonged *in-situ* observation is reported in Bagdassarov et al. (1996) who, consistent

376 with our results, found a decrease of bubble growth rates with time. Similarly, Bai et

377 al. (2008), using microtomographic *in-situ* measurements, observed that bubble

378 growth was faster in the first 10-20 s and then progressively decreased with time. In

379 general, the classic theory of bubble growth (where $R \sim t^{1/2}$; Proussevich and Sahagian

380 1998) offers a good approximation to these experimental observations, despite the

381 magnitude of the process may be dependent on factors like the amount of volatiles

382 dissolved and the composition of the melt. On the other hand, theoretical model

383 cannot be used to predict the bubble size distribution (BSD) and its evolution with

384 time, but rather, *in-situ* experiments provide the more reliable evidence on how

385 bubble growth mechanisms affect the evolution of BSD.

386   The three melt compositions showed a different evolution of the BSD, with

387 basalt and rhyodacite showing the least and most sorted distribution, respectively

388 (Figure 7). During all the experiments, the distribution of bubbles in the rhyodacitic

389 melt remained more homogeneous than in basalt and andesite, which, on the contrary,

390 evolved into poorly sorted distributions (Figure 2, Figure 7). The close fit of the

391 exponential law to the cumulative distribution of rhyodacite evidences the higher

392 homogeneity of the BSD, compared to basalt and andesite, whose cumulative

393 distributions can be fitted by a power law in the intermediate region (Figure 8). Such

394 variability of BSD can be related to the variable rate of coalescence in the three melt

395 compositions. Specifically, faster rates of bubble coalescence (i.e., experiments with

396 basalt and andesite) are likely to produce much more heterogeneous distributions than

397 for slow rates (i.e., experiment with rhyodacite).

398   The striking effect of the coalescence rate C_R in modifying the BSD curves may

399 easily lead to a misinterpretation of the texture of volcanic rocks. For example, the

400 occurrence of multiple modes in the BSD of basalt and andesite (Figure 7) could be

401 interpreted by means of secondary nucleation events (Klug et al. 2002; Polacci et al.

402 2003; Lautze and Houghton 2007) that actually did not occur during the experiments.

403 Rather, our observations suggest that the faster C_R in these two melts amplified the

404 effect of proportionate growth (i.e., growth rate proportionate to the size of the

405 bubble) that, shortly after the beginning of vesiculation, produced right skews and

406 multiple modes in the BSD. Proportionate growth is also visible in the BSD of

407 rhyodacite, the left tail of which indicates the persistence of small bubbles that grew

408 much less than larger ones, as a result of the much slower C_R of this melt, as

409 compared to basalt and andesite.

410

411   *4.3 Evolution of bubble number density (N_B)*

412   The initial bubble number density at nucleation can be estimated by

413 extrapolating the curves for N_B to the time zero of the experiment (Figure 6 a). These

414 values range from $7.9*10^4$ to $1.8*10^5$ mm^{-3} and match previous determinations of N_B

415 obtained by *in-situ* experiments on H_2O-saturated haplogranitic composition (Gondé

416 et al. 2011). However, considering the differences in volatile content, temperature,

417 pressure and nucleation mechanism, this agreement may be fortuitous. Bulk volatile

418 concentration will influence the evolution of N_B over time, with high volatile contents

419 causing a faster decrease of N_B (Gardner et al. 1999). Accordingly, N_Bs calculated in

420 our experiments are up to two orders of magnitude higher than N_Bs reported in

421 literature for experimentally decompressed H_2O-saturated dacitic and rhyolitic melts

422 (Gardner and Ketcham 2011), as expected from the low volatile content of the melt.

423   Our experimental determinations of N_B overlap the values typical of natural

424 pumices, ranging between 10^4 and 10^7 mm^{-3} (Polacci et al. 2001; Klug et al. 2002;

425 Colucci et al. 2013), whereas they are higher than N_B of less explosive products,

426 which typically range between 10^1 and 10^3 mm^{-3} (Parcheta et al. 2013).

427

428   *4.4 Effect of temperature and melt composition on volatile exsolution*

429   Bubble nucleation density and growth rates are controlled by the volatile

430 diffusivity of the melt that, in turn, depends on the polymerization of the melt

431 (NBO/T). This is because nuclei of bubbles need to exceed critical size to continue to

432 grow spontaneously and even a bubble of 0.1 μm size contains in the order of 10^6

433 molecules of CO_2 or H_2O, which have to be transported to the bubble by diffusion.

434 Melt characterized by lower diffusivity are likely to be characterised by higher N_B at

435 nucleation, because of the smaller volume of melt feeding each bubble. Consistently,

436 the experiment performed with rhyodacite at 1100 °C showed higher N_B than the

437 experiments with andesite and basalt performed at 1200 and 1240 °C, respectively,

438 and another experiment performed with rhyodacite at 1200 °C. For CO_2, however,

439 bulk composition and NBO/T may have only a minor effect on diffusivity (Zhang and

440 Ni 2010). In this regard, it should be noted that the variation of N_B at nucleation in the

441 three compositions is within one order of magnitude, which is much less than the

442 overall variability observed in natural products. Rather, the difference of N_B among

443 the melt compositions investigated, in particular between basalt and rhyodacite,

444 increases with time. Therefore, with the increasing bubble size and interaction

445 between bubbles, melt viscosity probably controls the rates of bubble growth and

446 coalescence. In fact, despite the considerably higher degree of supersaturation,

447 rhyodacite shows remarkably slower growth and coalescence rates as compared to the

448 less viscous basaltic and andesitic melt.

449

450   *4.5 Implications for volcanic systems*

451   Degassing-induced crystallization is common in magmas experiencing syn-

452   eruptive decompression (Mastrolorenzo and Pappalardo 2006; Humpreys et al. 2008;

453   Brophy 2009; Martel 2012; Mollard et al. 2012). Our experiments suggest that there

454   may also be a reverse relationship, with crystal nucleation being a possible cause of

455   bubble nucleation. Indeed, bubble nucleation in basalt and andesite occurs despite the

456   relatively small degree of volatile supersaturation of the melt, because of the presence

457   of crystal nuclei that act as nucleation sites for bubble (Hurwitz and Navon 1994). By

458   analogy to our experimental observations, the incipient crystallization of a magma

459   upon cooling may trigger volatile release and possibly, explosive volcanic eruptions.

460   This situation is likely to occur in differentiating magmas that achieve a pseudo-

461   invariant temperature that, once crossed, undergo to significant increase of

462   crystallization (Fowler et al. 2007). An alternative scenario could be the emplacement

463   and cooling of a crystal-poor magma at shallow depths. Here, the very onset of

464   crystallization could trigger an eruption. The very high bubble number densities at

465   relatively small supersaturation that we observe in our experiments, suggest that this

466   mechanism could be quite important in nature. We also observe how melts of lower

467   viscosity (basalt and andesite) rapidly achieve heterogeneous bubble distributions and

468   a less dense bubble packing than high viscous ones. Indeed, melts of higher viscosity

469   (rhyodacite) are likely to maintain a denser bubble packing for longer time, being thus

470   more susceptible to brittle failure and fragmentation, when the tensile stress at the

471   inner walls of bubbles exceeds the tensile strength of the magma (Zhang 1999).

472

473   **5. Conclusions**

474   Moissanite cell experiments allowed the direct observation of bubble nucleation

475   and growth at magmatic conditions that are otherwise not directly accessible. The data

476   presented in this study are therefore complementary to studies of bubble growth

477   performed at high-pressure and/or using controlled decompression rates. Our

478   experiments suggest that bubbles can nucleate at very small degrees of supersaturation

479   simultaneously with the nucleation of crystals. This implies that incipient

480   crystallization upon magma cooling could be an important mechanism for triggering

481   volatile release and explosive eruptions already at small degrees of volatile

482   supersaturation.

483   Melt polymerization plays role in determining the bubble number density at
484 nucleation, whereas, the viscosity of the melt controls the rates of bubble growth and
485 coalescence. Magmas characterized by higher NBO/T and lower viscosity are likely
486 to exhibit lower bubble number density at nucleation and faster growth and
487 coalescence rates, compared to magmas characterized by lower NBO/T and higher
488 viscosity. As result, bubble size distribution curves may evolve to very different
489 shapes, from multi-modal, in the case of less viscous magmas, to well sorted, in the
490 case of the more viscous ones. Such variability remarks the striking effect of
491 coalescence in changing the bubble size distributions, which may easily yield to
492 misinterpreting the texture of natural rocks.

640 Figure 1 – Sequence of pictures of a moissanite cell experiment with rhyodacite
641 showing the moment of bubble nucleation close to the final experimental temperature
642 of 1100 °C (a-c), bubble expansion following the dilatation of the sample (d-e) and
643 contraction immediately afterwards (f-h). The time is given relative to the time t_0, at
644 which the temperature of the set point was reached.

645

646 Figure 2 – Snapshots of the experiments performed in moissanite cells using 50 μm
647 thick glassy disks of synthetic basalt (top), andesite (middle) and rhyodacite (bottom).
648 Bubbles in basalt and andesite show less homogeneous distributions than in

649 rhyodacite and less spherical shape, as results of the faster growth and the higher rate

650 of coalescence. Note the different time necessary to achieve comparable bubble size

651 and the different distribution of bubbles. Arrows indicate bubbles in the process of

652 coalescence.

653

654 Figure 3 – Sequence of pictures showing the coalescence of bubbles in rhyodacitic

655 melt at 1200 °C, as indicated by the arrows. Frames are taken in 1 s intervals. The

656 shapes of coalesced bubbles change from elliptical to spherical within few seconds.

657

658 Figure 4 - Sequence of pictures of an experiment performed with basalt, showing the

659 occurrence of Ostwald ripening. Compared to coalescence, Ostwald ripening is much

660 slower and involves bubbles of different size. The small bubbles near the larger one in

661 the top right corner (red arrows) are redissolved in the melt causing a slightly

662 perceptible increase of the volume of the large bubble.

663

664 Figure 5 – (a) Linear fitting of bubble size through time (t>20 s). Bubble growth at

665 t<20 s occurs much faster than after 20 s and can be approximated by a logarithmic

666 law. (b) Bubble growth rates (G_R) calculated by the derivative with respect to time of

667 the growth laws.

668

669 Figure 6 – (a) Variation of bubble number density (N_B) and (b) coalescence rate (C_R)

670 with time. The coalescence rate expresses the number of coalescence events ($mm^{-3}*s^{-1}$

671) and is calculated from the derivative of the N_B curves with respect to time.

672

673 Figure 7 – Evolution of bubble size distribution (BSD) through time for the three

674 different melt compositions. The area of the bubble is plotted instead of the radius, in

675 order to increase the number of bins that can be plotted and to reduce the error of the

676 determination of the radius from the area obtained from image analyses. Each bin

677 corresponds to a class of bubble area calculated on basis 2 (e.g., 0-2 μm^2, 2-4 μm^2, 4-

678 8 μm^2, etc.). Note how distributions in basalt and andesite achieve in a relatively short

679 time poorly sorted distributions, whereas rhyodacite maintains through time a well-

680 sorted distribution.

681

682 Figure 8 – Log-Log plot of cumulative bubble size distribution. The number of
683 bubbles is normalized to the volume of the sample. The overall distribution follows an
684 exponential law for all the three compositions, with the rhyodacitic melt showing the
685 best fitting (panels on the left). In the central segment, the distribution of basalt and
686 andesite show the best fitting with a power law, which exponential term increases
687 with time producing a counterclockwise rotation of the fitting line (panels on the
688 right).

Table 1. Electron microprobe analyses of glasses used as starting material and FTIR measurements of the volatiles in the melt.

	Basalt (18) T_{exp}=1240 °C T_{liq}=1220 °C	Andesite (17) T_{exp}=1200 °C T_{liq}=1150 °C	Rhyodacite (16) T_{exp}=1100 °C T_{liq}=1090 °C
SiO_2	50.64 (0.29)	57.90 (0.44)	68.65 (0.29)
TiO_2	0.85 (0.05)	0.85 (0.08)	0.55 (0.04)
Al_2O_3	16.45 (0.22)	17.87 (0.51)	14.30 (0.15)
FeO_{tot}	-	-	3.49 (0.08)
MnO	8.08 (0.12)	5.87 (0.16)	-
MgO	7.60 (0.14)	4.21 (0.11)	1.46 (0.06)
CaO	10.39 (0.14)	6.98 (0.17)	3.95 (0.07)
Na_2O	3.27 (0.11)	3.25 (0.12)	3.61 (0.08)
K_2O	2.16 (0.07)	2.64 (0.21)	3.09 (0.09)
Total	99.45 (0.34)	99.57 (0.33)	99.10 (0.31)
H_2O (ppm)	13 (1)	19 (3)	408 (26)
CO_2 (ppm)	101 (10)	289 (29)	1135 (114)
H_2O (vol.%)[a]	17.5	23.6	84.3
CO_2 (vol.%)[a]	33.4	57.3	81.8
Bubble vol. (%)[b]	16	13	30

T_{exp}: temperature at which the experiment is performed

T_{liq}: liquidus temperature calculated using MELTS

([a]) Volume produced by the exsolution of the single volatile component present in the melt (either H_2O or CO_2) calculated at 1 atm and at different experimental temperatures, assuming an ideal behavior of the gas phase (PV=nRT). Note that these values are much greater than the total volume of the gas phase observed at the end of the experiment ([b]), indicating some volatiles remained in the melt.

Table 2. Results from image analyses.

Basalt				
Exp. time (s)	30	300	540	900
Ave. Rad. (μm)	4.06	4.68	5.72	6.96
Std. Dev.	1.14	2.37	3.35	4.84
Porosity (φ)	0.063	0.065	0.095	0.157
N_B (mm^{-3})	$8.46*10^4$	$7.92*10^4$	$5.19*10^4$	$3.55*10^4$
G_R (mm*s^{-1})[a]	$1.35*10^{-4}$	$2.31*10^{-6}$	$4.32*10^{-6}$	$3.45*10^{-6}$

Andesite				
Exp. time (s)	45	165	735	2644
Ave. Rad. (μm)	4.13	5.04	5.78	9.04
Std. Dev.	1.68	2.72	2.77	4.87
Porosity (φ)	0.044	0.068	0.076	0.137
N_B (mm^{-3})	$9.33*10^4$	$6.10*10^4$	$5.37*10^4$	$2.10*10^4$
G_R (mm*s^{-1})[a]	$9.18*10^{-5}$	$7.54*10^{-6}$	$1.30*10^{-6}$	$1.71*10^{-6}$

Rhyodacite				
Exp. time (s)	480	7207	14974	18394
Ave. Rad. (μm)	3.40	5.14	8.65	13.35
Std. Dev.	1.38	2.08	2.89	4.80
Porosity (φ)	0.06	0.096	0.184	0.297
N_B (mm^{-3})	$1.72*10^5$	$9.01*10^4$	$3.77*10^4$	$1.54*10^4$
G_R (mm*s^{-1})[a]	$7.08*10^{-6}$	$2.59*10^{-7}$	$4.52*10^{-7}$	$1.37*10^{-6}$

([a]) Growth rate (G_R) is calculated for each segment Δt.
