UNIVERSITÀ DI PISA
DIPARTIMENTO DI SCIENZE DELLA TERRA

Pisa, August the 3rd, 2019

Dear Editor,

we submit a paper entitled

"**Strontium Isotope Stratigraphy of the Miocene sedimentary successions of the East Pisco Basin (Peru): new age constraints and paleoclimatic implications**"

by Giulia Bosio *et alii* for publication in *Journal of South American Earth Sciences* as a regular research article.

The marine deposits of the East Pisco Basin of southern Peru are of global interest because of their rich and exceptionally preserved fossil assemblage. Recent work has redefined and dated much of the local Miocene succession, comprising the lower Miocene Chilcatay and the upper Miocene Pisco formations. Crucially, however, a large gap remains between these two units, with the age of the lowest portion (P0 sequence) of the Pisco Formation remaining unknown. Here, we address this issue via Strontium Isotope ($^{87}Sr/^{86}Sr$) Stratigraphy dating carbonates (mollusks, barnacles, and nodules) and phosphates (shark teeth) from both formations. To avoid diagenetic bias, the suitability of shells was first assessed via optical and scanning electron microscopy, cathodoluminescence, and inductively coupled plasma-optical emission spectrometry. Likewise, only the best-preserved shark teeth were sampled for analysis. Our results confirm a Burdigalian age for the Chilcatay Formation and date P0 to the middle Miocene, which matches the relatively archaic aspect of its cetacean fossil assemblage. The depositional environment of P0 resembles the warm conditions associated with the Chilcatay Formation, rather than the cooler setting inferred for the remainder of the Pisco Formation. This pattern may reflect a middle or early late Miocene strengthening of the Humboldt Current.

We thought that this issue may be of interest for *Journal of South American Earth Sciences* and we decided thus to submit our work to Your attention. We would like to inform You that: 1) all the authors of this paper agree on its submission; 2) this article substantially relies on original data, it has not been published before, and is not concurrently being considered for publication elsewhere; 3) we have no competing interests; 4) this article does not violate any copyright or other personal proprietary right of any person or entity and it contains no abusive, defamatory, obscene or fraudulent statements, nor any other statements that are unlawful in any way.

We hope that our paper will interest You and will be suitable for publication in Your journal, and we look forward for receiving Your decision letter.

Sincerely Yours,
the Corresponding Author:

Highlights

- We applied Sr isotope dating to carbonates and phosphates from the East Pisco Basin

- $^{87}Sr/^{86}Sr$ values date the lower Pisco strata (P0 sequence) to the middle Miocene

- Paleontological data indicate a warm water paleoenvironment for P0

- Our results suggest a middle-late Miocene strengthening of the Humboldt Current

Abstract

The marine deposits of the East Pisco Basin (Peru) are of global interest because of their rich and exceptionally preserved fossil assemblage. Recent work has redefined and dated much of the local Miocene succession, comprising the lower Miocene Chilcatay and the upper Miocene Pisco formations. Crucially, however, a large gap remains between these two units, with the age of the lowest portion (P0 sequence) of the Pisco Formation remaining unknown. Here, we address this issue via Strontium Isotope ($^{87}Sr/^{86}Sr$) Stratigraphy dating carbonates (mollusks, barnacles, and nodules) and phosphates (shark teeth) from both formations. To avoid diagenetic bias, the suitability of shells was first assessed via optical and scanning electron microscopy, cathodoluminescence, and inductively coupled plasma-optical emission spectrometry. Likewise, only the best-preserved shark teeth were sampled for analysis. Our results confirm a Burdigalian age for the Chilcatay Formation and date P0 to the middle Miocene, which matches the relatively archaic aspect of its cetacean fossil assemblage. The depositional environment of P0 resembles the warm conditions associated with the Chilcatay Formation, rather than the cooler setting inferred for the remainder of the Pisco Formation. This pattern may reflect a middle or early late Miocene strengthening of the Humboldt Current.

1. Introduction

The $^{87}Sr/^{86}Sr$ ratio of Sr (strontium) isotopes dissolved in the global ocean has varied through the geological time (McArthur, 1994; McArthur et al., 2012). At the same time, the world's seas are homogeneous with respect to $^{87}Sr/^{86}Sr$ ratio, and this is assumed for any

55   geologic time (McArthur et al., 2012). Therefore, Sr isotope composition can be used for

56   dating marine minerals and correlating marine sedimentary successions worldwide (Faure

57   and Mensing, 2005). Application of Strontium Isotope Stratigraphy (hereinafter: SIS)

58   requires measurement of the Sr isotope ratio of minerals that precipitated from seawater and

59   have not undergone diagenetic alteration of their original $^{87}Sr/^{86}Sr$ value (McArthur et al.,

60   2012). Some intervals of geological time, such as the Miocene, are particularly favorable for

61   implementation of SIS because they display high rates of change of the $^{87}Sr/^{86}Sr$ value and a

62   narrow error band on the empirically defined reference curve (McArthur et al., 2012), which

63   allow for high-resolution age estimates.

64   The Miocene Chilcatay and Pisco formations exposed in the East Pisco Basin of southern

65   Peru are renowned for their exceptional fossil assemblage, comprising cetaceans, seals,

66   sharks, rays, crocodiles, turtles, seabirds, and bony fishes (e.g., Bianucci et al., 2015, 2016 a,

67   b, c, 2018a, b; Collareta et al., 2017; Lambert et al., 2014, 2015, 2017 a, b, 2018; Landini et

68   al., 2017 a, b, 2019; Marx et al., 2017a, b; Gioncada et al., 2018b) as well as marine

69   invertebrates (e.g., DeVries and Frassinetti, 2003; DeVries et al., 2006; DeVries, 2016;

70   Coletti et al., 2018, in review; Collareta et al., 2019). To put this assemblage into context,

71   reliable age estimates are crucial. Recent work established a chronostratigraphic framework

72   based on $^{39}Ar–^{40}Ar$ dating, tephrostratigraphy and biostratigraphy, which dates the Chilcatay

73   Formation to the early Miocene and the upper sequences of the Pisco Formation to the late

74   Miocene, respectively (Di Celma et al., 2017, 2018a, b; Gariboldi et al., 2017; Bosio et al.,

75   2019, in press). The seemingly large temporal gap between these two units is striking, but is

76   almost certainly an overestimate caused by a lack of datable ash layers and microfossils from

77   the lowermost portion of the Pisco Formation (the P0 sequence). Previous studies remarked

78   on the significantly archaic aspect of the cetacean fauna from this layer (Di Celma et al.

79   2017; Marx et al. 2017b), but were unable to draw definitive conclusions as to its age. The

80 peculiar faunal changes that characterize this unit (Di Celma et al., 2017) make the dating of

81 these strata an issue of prime importance for the ongoing paleontological studies on the

82 Miocene fossil content of the East Pisco Basin.

83   Here, we present the first attempt to date the lower Pisco beds by means of SIS. Mollusk

84 (i.e., ostreids and pectinids) and barnacle shells, diagenetic cements, bulk sediment samples,

85 and shark teeth were collected to apply this method to both carbonates and phosphates.

86 Several samples from the age-constrained Ct1 sequence of the Chilcatay Formation were

87 dated for checking the reliability of the Sr results in the study areas. The preservation state of

88 the invertebrate remains was preliminary addressed via petrographic, morphological,

89 chemical, and cathodoluminescence analyses in order to quantify the extent of diagenetic

90 alteration and to assess whether the shells were structurally and chemically pristine. Sr

91 isotope ratios were elaborated with the LOWESS Table 5 made for the GTS2012 timescale

92 (McArthur et al., 2012) and SIS ages were obtained.

93   Furthermore, we investigate the faunal assemblages of both fossil invertebrates and

94 vertebrates for reconstructing the paleoenvironment of the P0 sequence. The

95 paleoenvironmental and stratigraphic significance of this unit is then addressed in the light of

96 our age estimates.

97

98 **2. Geological setting**

99   Since the Mesozoic, the geodynamics of Peru have been defined by the convergence of the

100 oceanic Nazca/Farallon Plate and the continental South American Plate, creating a composite

101 transform-convergent margin with a series of elongated extensional/pull-apart basins (e.g.,

102 Kulm et al., 1982; Dunbar et al., 1990; León et al., 2008; Zúñiga-Rivero et al., 2010). Two

103 trench-parallel structural highs further divide the Peruvian offshore into a series of outer (i.e.,

104 seaward) and inner sedimentary basins (Thornburg and Kulm, 1981) (Fig. 1A). The East

5

105   Pisco Basin falls into the latter category, and today is evident as a 180 km-long depression

106   paralleling the coast of southern Peru between the towns of Pisco and Nazca. Its rise above

107   sea level is due to the subduction of the nearby Nazca Ridge, a region of topographically high

108   oceanic crust impinging on the Peru-Chile trench (Pilger, 1981; Hsu, 1992; Macharé and

109   Ortlieb, 1992; Hampel, 2002). The basin infill comprises, in stratigraphic order, the Eocene

110   Caballas and Paracas formations, the upper Eocene to lower Oligocene Otuma Formation,

111   and the largely Miocene Chilcatay and Pisco formations (Dunbar et al., 1990; DeVries, 1998,

112   2017; DeVries et al., 2017; DeVries and Jud, 2018). These units are bounded by regionally

113   extensive unconformities marking major breaks in the sedimentary record, commonly

114   demarcated by pavements of igneous pebble-boulder clasts indicative of subaerial exposure;

115   moreover, intraformational unconformities are also present (DeVries, 1998; Di Celma et al.,

116   2017, 2018a, b). Therefore, this succession has been classified using both a lithostratigraphic

117   (formations) and an allostratigraphic (allomembers) approach (North American Commission

118   on Stratigraphic Nomenclature [NACSN], 2005). In the present paper, we maintain the

119   lithostragraphic classification for the formations and identify within them a number of

120   informal units, defined in the study area by unconformities, as sequences (the unconformities

121   observed in the study area are actually sequence boundaries). This subdivision could be

122   applied also basinward, whenever these unconformities may pass to correlative conformities.

123   During deposition of the Chilcatay and Pisco formations, the East Pisco Basin was a semi-

124   enclosed, shallow-marine bay, structured along a latitudinal depth gradient, and sheltered

125   seawards by a longshore chain of crystalline basement islands (Fig. 1B) (Marocco and

126   Muizon, 1988; DeVries and Jud, 2018; Bianucci et al., 2018b). The Chilcatay Formation is

127   composed of two distinct sequences, namely, Ct1 and Ct2; the former includes three facies

128   associations, recording deposition in shoreface, offshore, and subaqueous delta, whereas the

129   latter includes two facies associations, recording deposition in shoreface and offshore settings

6

130 (Di Celma et al., 2018b, 2019). The chronostratigraphic framework of these outcrops is well

131 constrained by integration of micropaleontological data and isotope geochronology. Diatom

132 biostratigraphy suggests deposition of the Chilcatay sediments exposed at Ullujaya between

133 19 and 17 Ma (Burdigalian), whereas the ^{39}Ar–^{40}Ar radiometric age of an ash layer from the

134 uppermost portion of the Ct2 sequence indicates deposition at 18.02 ± 0.07 Ma (Di Celma et

135 al., 2018b; Bosio et al., in press). The Pisco Formation is composed of three fining-upward

136 sequences, designated P0, P1, and P2 from oldest to youngest, which are divided by three

137 unconformities, named PE0.0, PE0.1, PE0.2, respectively, and progressively onlap a

138 composite basal unconformity from southwest to northeast. Each unit, representing a

139 transgressive cycle, recorded deposition in shoreface (sandstones) and in offshore

140 (siltstones/diatomaceous siltstones). The time of deposition of the P1 and P2 sequences is

141 constrained, thanks to diatom biostratigraphy and ^{39}Ar–^{40}Ar ages of tephra, between 9.5 Ma

142 and 8.6 Ma, and between 8.4 and 6.7 Ma, respectively (Gariboldi et al., 2017; Bosio et al., in

143 press). Due to the lack of tephra layers and microfossils, the depositional age of the lower

144 unit, P0, is to date very poorly constrained between 18.02 ± 0.07 Ma and 9.46 ± 0.05 Ma (Di

145 Celma et al., 2017; Bosio et al., in press). Note, however, that DeVries and Jud (2018)

146 previously proposed an early–middle Miocene age for the lower portion of the Pisco

147 Formation (including P0), based on a series of diatom samples analyzed by H. Schrader in the

148 1980s.

149

150 **3. Stratigraphy and fossil assemblage of the Ct1 and P0 sequences**

151 At Ullujaya and Roca Negra, two localities along the western side of the Ica River (Fig.

152 2A), the lower sequence (Ct1) of the Chilcatay Formation consists of massive sandstones and

153 conglomerates with boulder-sized clasts at the bottom (*Ct1c* facies association), followed by

154 medium- to fine-grained sandstones alternating with conglomerate beds (*Ct1a*), and

clinobedded coarse-grained calcirudites at the top (*Ct1b*) (Di Celma et al., 2018b, 2019).

These facies associations record deposition in the shoreface, offshore, and on a mixed

siliciclastic-carbonate subaqueous delta, respectively (Di Celma et al., 2019), and suggest a

semi-protected embayment associated with both a river mouth and the open ocean (Bianucci

et al., 2018b).

The invertebrate fossil assemblage of Ct1 is concentrated into discrete layers, and

comprises mollusks, barnacles, serpulids and echinids (Di Celma et al., 2018b). Bivalves are

represented by ostreids, pectinids and venerids. Barnacles mainly belong to three taxa, with

Austromegabalanus carrioli being the most abundant (Coletti et al., 2018; Collareta et al.,

2019). The vertebrate fossil assemblage is dominated by toothed cetaceans (Odontoceti),

including kentriodontids (*Kentriodon* sp.), squalodelphinids (*Notocetus vanbenedeni* and

Huaridelphis raimondii), physeteroids (sperm whales), platanistid-like longirostrine

homodont forms, eurhinodelphinids, and the eurhinodelphinid-like *Chilcacetus* (Bianucci et

al., 2015, 2018b; Lambert et al., 2014, 2015; Di Celma et al., 2018b, 2019). In addition, there

are sea turtles (large-sized indeterminate dermochelyids), bony fishes and elasmobranchs,

with abundant juvenile teeth of the bronze shark *Carcharhinus brachyurus* and the extinct

lamniform *Cosmopolitodus hastalis*. Overall, the fossil assemblage points to a coastal

community dominated by warm-water mesopredators (Bianucci et al., 2018b).

The P0 strata of the Pisco Formation reach their maximum thickness (about 40 m) at the

locality of Cerro Submarino. This unit is mostly composed of fine- to very coarse-grained,

cross-stratified, fossil-rich sandstones, suggesting a very nearshore environment (Di Celma et

al., 2017).

The fossil invertebrate assemblage is dominated by mollusks, with barnacles being less

common. Bivalves primarily include *Chionopsis* spp. and *Dosinia ponderosa*, but *Miltha* cf.

vidali and ostreids are also present. Gastropods mainly belong to the family

180 Architectonicidae, in addition to cypraeids and one specimen of *Ficus distans* (Di Celma et

181 al., 2017). Finally, the assemblage includes the only known occurrence of a rhizangiid coral

182 in the East Pisco Basin, reported in this paper for the first time.

183   Vertebrates are abundant, but less studied than those from the underlying Chilcatay strata

184 (Di Celma et al., 2017; Marx et al., 2017b; Bianucci et al., 2019). Baleen whales (Cetacea:

185 Mysticeti) dominate the assemblage and are represented by i) a large-sized stem

186 balaenopteroid, *Pelocetus* sp.; ii) the archaic cetotheriid *Tiucetus rosae*, previously described

187 from the southeastern locality of Santa Rosa (Marx et al., 2017b), but also present at other

188 sites with better-constrained stratigraphy and P0 exposures along the western side of the

189 lower Ica valley; and iii) a third form, previously identified as a cetotheriid (Di Celma et al.,

190 2017), but here more conservatively reinterpreted as an indeterminate plicogulan. Toothed

191 whales include at least one physeteroid and two kentriodontid-like delphinoids. In addition,

192 there are fragmentary fossils of chelonioid turtles and longirostrine crocodilians, and a single

193 bird specimen representing an indeterminate pelagornithid. Shark and ray teeth are relatively

194 common and include, among others, *Anoxypristis* sp., *Carcharhinus* spp., *Carcharocles*

195 *megalodon*, *Cosmopolitodus hastalis*, *Hemipristis serra*, *Isurus oxyrinchus* and myliobatids

196 (eagle rays).

197

198 **4. Material and Methods**

199 *4.1. Study area and sample collection*

200   The study area is settled in the Ica desert, at the localities of Roca Negra and Ullujaya,

201 where the Chilcatay Formation crops out (Di Celma et al., 2018b, 2019; Bianucci et al.,

202 2018b), and Cerro Submarino, where P0 displays its maximum thickness (Fig. 2A).

203   Samples collected for applying the SIS were carbonates (invertebrate shells, cements) and

204 phosphates (shark teeth). For the Sr isotope analyses, shark tooth fluorapatite and low-Mg

calcite shells were preferred, as low-Mg calcite is more stable, more resistant to diagenesis

and less soluble than other carbonates (Brand, 1991; Steuber, 2003). Mollusks (i.e., ostreids

and pectinids) and barnacles, shark teeth, and bulk and cement samples were collected along

the measured section of the well-dated Chilcatay Formation at Roca Negra (14°39'04"S;

75°38'54"W) and Ullujaya (14°34'59"S; 75°38'27"W), as well as from the undated P0

deposits at Cerro Submarino (14°34'38"S; 75°39'51"W) (Fig. 2A). Different horizons were

selected at each locality (Fig. 2B, C) and, for each level, several carbonate shells were

sampled, usually from different organisms (e.g., oysters, pectinids, and barnacles). Some bulk

and cement samples were also analyzed for better understanding the diagenetic path and its

effects on $^{87}Sr/^{86}Sr$ values.

4.2. Optical microscopy (OM), scanning electron microscopy (SEM), and

cathodoluminescence

Diagenetic processes or weathering could modify the pristine $^{87}Sr/^{86}Sr$ ratio of carbonate

and phosphate marine minerals. As diagenetic or weathering modifications can affect the

analytical results, providing wrong ages of mineral formation (Scasso et al. 2001; Brand et al.

2012; Ullmann and Korte, 2015), their identification is critical for evaluating the reliability of

the $^{87}Sr/^{86}Sr$ ratio, which is suitable for SIS only when post-depositional alterations can be

excluded. With the aim of evaluating the impacts of diagenesis and wethering on shells,

mollusk and barnacle samples from both the Chilcatay and Pisco formations have been

prepared for realizing thin sections. Petrographic analyses of polished thin sections were

carried out through Leica and Olympus optical microscopes. A SEM-EDS Tescan VEGA TS

Univac 5136XM was used at the Department of Earth and Environmental Sciences of the

Università degli Studi di Milano-Bicocca for petrographic and morphological observations,

as well as for checking evidence of dissolution in the structure of the selected shells.

230 Cathodoluminescence was performed using a CITL Optical Cathodoluminoscope at the

231 Department of Earth Science "Ardito Desio" of the Università degli Studi di Milano, operated

232 at about 14kV accelerating voltage and 0.5 mA gun current intensity. Cathodoluminescence

233 observations permitted the identification of different carbonate generations, as well as of

234 recrystallized portions of the shells (Barbin, 2013; Ullman and Korte, 2015).

235   Pristine shells were chosen for the age calculation, but some recrystallized materials were

236 also selected for $^{87}Sr/^{86}Sr$ analyses, for understanding how diagenesis changed the Sr ratio

237 (i.e., diagenesis path) (Steuber, 2003). Regarding shark teeth, samples were taken from the

238 outer enameloid layer, avoiding dentine, which is generally more porous and susceptible to

239 diagenetic alteration than enameloid (Becker et al., 2008; Enax et al., 2014).

240   After the preliminary analyses, fifteen samples were selected from the Ct1 sequence of the

241 Chilcatay Formation, whereas eight samples were selected from the P0 sequence of the Pisco

242 Formation (Table 1).

243

244 *4.3. Compositional and strontium isotope analyses*

245   After microscopic investigations, the selected pristine mollusk shells and well-preserved

246 barnacle sheaths were carefully cleaned through an ultrasonic bath in distilled water. They

247 were bored with a Dremel micro-drill to obtain shell powder from the diagenetically

248 unaltered portion. After an ultrasonic bath in distilled water, the selected shark teeth were

249 also scraped as powder of their unaltered, non-porous enameloid was collected with the

250 micro-drill. About 10-50 mg of each sample were collected for inductively coupled plasma-

251 optical emission spectroscopy (ICP-OES) and $^{87}Sr/^{86}Sr$ analyses, taking care to avoid

252 contaminations.

253   ICP-OES and $^{87}Sr/^{86}Sr$ analyses were made at the Institute für Geologie, Mineralogie und

254 Geophysik of the Ruhr-Universität of Bochum. ICP-OES analyses were made with a Thermo

255   Fisher Scientific iCAP 6500 DUO spectrometer for analyzing the concentrations of Sr, Ca

256   (calcium), Mg (magnesium), Fe (iron), and Mn (manganese).

257    $^{87}Sr/^{86}Sr$ ratios were determined with a TIMS Finnigan MAT 262 solid source mass

258   spectrometer with seven collectors, using a dynamic (peak-hopping) mode of measurement.

259   The cut-off limit for a strontium run was an error of $\pm 2\sigma \leqslant 5 \times 10^{-6}$ for the $^{87}Sr/^{86}Sr$ ratio,

260   with 100–200 ratios per run (typical duration: 110 ratios, lasting 2 h 15 min, plus the filament

261   heating time). Two standards – NIST NBS 987 and USGS EN-1 – were used to calibrate the

262   analysis. NIST NBS 987 was loaded directly onto the filament, to confirm the stability of the

263   mass spectrometer. USGS EN-1, a powder derived from a modern *Tridacna* shell, underwent

264   the same procedure as the other carbonate samples, to ensure the reproducibility of the entire

265   analytical process. Thirty-four analyses of NIST NBS 987 resulted in a mean of 0.710240 ±

266   0.000023 (2σ), while 24 analyses of USGS EN-1 yielded 0.709153 ± 0.000019 (2σ). No Rb

267   (rubidium) correction was applied, but Rb was nonetheless monitored during the entire run.

268   When Rb levels exceeded the detection limit, the result was discarded and the measurement

269   repeated.

270   The results of the $^{87}Sr/^{86}Sr$ analyses were corrected for the difference between the USGS

271   EN-1 value used for the compilation of the reference curve (McArthur et al., 2012) and the

272   USGS EN-1 Bochum mean value, and then converted into ages using the LOWESS Table 5,

273   which is tied to the GTS2012 timescale (McArthur et al., 2012). The latter is still incomplete,

274   therefore the results were rounded off to the nearest value. Following the method described

275   by Frijia et al. (2015), when more than one sample was analyzed for a single layer, a mean

276    $^{87}Sr/^{86}Sr$ value was calculated. The uncertainty for each stratigraphic level was calculated as 2

277   s.e. (i.e., standard error) from the standard deviation of the mean.

278

279   **5. Results**

5.1. Diagenesis evaluation

281   The Chilcatay and Pisco formations present notably divergent patterns of carbonate

282   preservation. In the Chilcatay Formation, fossil invertebrates are well-preserved and retain

283   their pristine calcitic shells. In contrast, in the Pisco Formation, calcitic shells are only

284   present in the P0 sequence, where examples of calcite recrystallization also occur, but not in

285   P1 and P2, where mollusks are only preserved as casts (Di Celma et al., 2017). For these

286   reasons, SIS could only be applied in the Ct1 and P0 sequences, once some caveats have been

287   taken into account.

288   At the macroscale, all of the bivalves selected for Sr analyses from both the units appear

289   well-preserved and composed of calcite. The oysters (Fig. 3A) are usually incided by

290   attachment traces by sponges and/or drill holes due to the predatory action of carnivorous

291   gastropods; in several cases, they preserve layers of unaltered nacre. The pectinids (Fig. 3B)

292   are also well-preserved, with small borings and some barnacle attachment traces

293   (*Anellusichnus*; Santos et al., 2005). By contrast, the barnacles (Fig. 3C) generally display

294   obvious signs of abrasion and lack their opercula; the best-preserved and less porous portion

295   of the shell is often constituted by the sheath, the thickened upper part of the inner wall.

296   Shark teeth selected for Sr analyses are moderately- to well-preserved; although two shark

297   teeth show a breakage surface in their root, they all have an intact thin layer of enameloid that

298   surrounds the pulp cavity and covers the surface of the tooth crown (Fig. 3D).

299   Microscopically, the best-preserved pectinids and ostreids are characterized by foliated

300   and prismatic calcite, respectively (Fig. 4A, C) (Cox et al., 1971). Both also have a low,

301   homogeneous luminescence, suggesting little or no diagenesis (Fig. 4B, D). Nevertheless,

302   some of the analyzed ostreids also have layers that are luminescent, documenting diagenetic

303   modifications. Microborings filled by luminescent calcite or terrigenous sediments, can be

304   observed. These infills must be avoided during sampling for Sr isotope analyses, because

they could have non-pristine Sr ratio (Fig. 4C, D). As reported also by Crippa et al. (2016),

fossil ostreids occasionally exhibit layers of sparry calcite replacing the pristine aragonitic

layers (i.e., myostracum) or filling the chambers once permeated by organic matter (Fig. 4E,

F). All those specimens that present similar features were discarded from the Sr analyses.

Several oysters from the Ct1 and P0 sequences that exhibit a generally low luminescence

have discrete luminescent layers that appear pristine and prismatic. For explaining this

feature, which has also been documented in modern oysters, Barbin (1991, 2013) argued that

luminescence may not be always a convincing indicator of diagenetic alteration for oysters,

because the absorption of Mn^{2+} by benthic organisms depends on various factors, such as

growth rate, ontogeny, bathymetry and salinity. To minimize the risk of diagenetic bias, we

conservatively discarded all the ostreid samples with diffuse microborings, sparry calcite, or

displaying high and/or heterogeneous luminescence. By contrast, the best-preserved

barnacles are characterized by low luminescence throughout the less porous portion of the

wall, but high luminescence charaterized the parietal tubes, which are normally filled with

secondary calcite (Fig. 4G, H). We carefully avoided to contact the parietal tubes during

sampling of the barnacle shells for the strontium analysis.

Secondary electron (SE) images confirmed the presence of alternating prismatic and

sparry calcite layers in some ostreid specimens (Fig. 5A, B) that were hence discarded. Other

specimens either retain a pristine prismatic layer (Fig. 5C) or show clear signs of alteration,

with the prismatic layer being unrecognisable, very irregular, or dissolved (Fig. 5D). Again,

specimens exhibiting obvious evidence of diagenesis were discarded.

ICP-OES analysis is useful for measuring the Fe, Mn, Mg, and Sr concentrations, which in

turn can be informative in terms of diagenetic imprint on carbonates. Usually, the Fe and Mn

contents of carbonates increase during the diagenetic processes; on the contrary, the Mg and

Sr contents generally decrease during diagenesis (Brand and Veizer, 1980; McArthur, 1994;

14

330   Steuber, 1999). In Figure 6A, the low Sr content of cement and bulk samples indicates a

331   decrease in Sr during diagenesis, as reported by Frijia and Parente (2008) for diagenetically

332   altered marine carbonates, coupled with a decrease of the $^{87}Sr/^{86}Sr$ value. The latter trend is

333   opposite to what is normal observed in diagenetically altered carbonates, when the interaction

334   of the diagenetic fluids with siliciclastic rocks generally results in more radiogenic Sr isotope

335   values (McArthur, 1994). The decrease of the Sr ratio in the diagenetically altered calcite of

336   the studied successions can be due to the pre-Miocene seawater-derived brine circulating

337   within the sedimentary sequence, as reported by Gioncada et al. (2018a). This decrease of the

338   Sr isotope ratio from pristine to diagenetic calcite confers older Sr ages to the diagenetically

339   altered samples. The abundance of Fe and Mn in the diagenetic samples (see Fig. 6B, C, D)

340   conforms to the expected pattern of increasing Fe and Mn concentration during diagenesis.

341   The above reconstruction of the diagenetic paths helps in assessing the preservation of each

342   sample. Indeed, samples displaying the same degree of morphological preservation but higher

343   concentrations of Sr and lower concentrations of Fe and Mn might be considered as retaining

344   the pristine Sr isotope ratio of seawater.

345

346   *5.2. Strontium Isotope Stratigraphy of the Ct1 sequence*

347   After discarding all those shells that may have been affected by post-depositional

348   modifications, fifteen samples from the Ct1 sequence of the Chilcatay Formation (Ullujaya

349   and Roca Negra) were selected for $^{87}Sr/^{86}Sr$ analysis (Table 2). From each locality, Sr isotope

350   analyses of different well-preserved shells yielded similar Sr isotope values. The internal

351   consistency of the Sr isotope ratios of different samples from the same stratigraphic level can

352   be regarded as a strong argument supporting the preservation of the original seawater

353    $^{87}Sr/^{86}Sr$ value (McArthur et al.,1994; Steuber, 2003).

354   At Roca Negra, we sampled three well-preserved oysters (PN-OST, PN-GIO1, PN-GIO2)

355   from the *Ct1c* facies association. The three specimens came from a single bed (PN Oyster

356   level; Fig. 2) close to the base of the formation, ten meters above an ash layer (PN-T2) dated

357   to 19.25 ± 0.05 Ma (Bosio et al., in press). Sr isotope analyses give similar $^{87}Sr/^{86}Sr$ results

358   (Table 2) and the mean value gives a preferred age of 18.50 with a range of uncertainty

359   spanning between 18.85 and 18.15 Ma (Table 3). This SIS age is in agreement with the older

360   age (i.e., 19.25 Ma) of the PN-T2 ash layer, sampled ten meters below.

361   At Ullujaya, we sampled 12 specimens from the *Ct1a* facies association, whose age is

362   constrained by a basal ash layer (UJA-T35) dated to 19.00 ± 0.28 Ma (Bosio et al., in press),

363   and by a second ash layer in the overlying *Ct2b* facies association (SOT-T3; Fig. 2) dated to

364   18.02 ± 0.07 Ma (Di Celma et al., 2018b).

365   Three samples – a barnacle sheath (UL-LIVa), composite sample of two pectinids (UL-

366   LIVb), and a further, single pectinid (UL-LIVc) – were chosen from a layer 9 m above the

367   base of the measured section (hereafter: abs), named "mollusk- and barnacle-rich horizon" by

368   Collareta et al. (2019) (Fig. 2). The mean value of the $^{87}Sr/^{86}Sr$ values gives again a preferred

369   age of 18.50 Ma and an uncertainty that ranges from 18.60 to 18.40 Ma for this horizon

370   (Table 3).

371   At 17 m abs, in occurrence of the key bed C (KbC of Di Celma et al., 2018b) (Fig. 2),

372   nacre layers of two well-preserved oysters were selected (UJA-LIVC1, UJA-LIVC3) together

373   with a barnacle sheath (UJA-LIVC4) (Table 1). In addition, a sample of the cemented bulk

374   sediment from the outer part of an oyster shell was also analyzed (UJA-LIVC2). Considering

375   only the ages from the pristine shells, we obtained similar $^{87}Sr/^{86}Sr$ values and Burdigalian

376   ages (see Table 2). The bulk sample UJA-LIVC2 shows a lower value of $^{87}Sr/^{86}Sr$ ratio and

377   gives older ages, suggesting an ageing effect caused by diagenesis, as discussed above. The

378   age range of the key bed C is thus comprised between 18.50 and 18.10 Ma, with a preferred

379 age of 18.30 Ma (Table 3). The SIS age of this bed is apparently younger than that of the bed

380 below (i.e., the mollusk- and barnacle-rich horizon), dated at ca. 18.50 Ma, although the two

381 obtained age ranges are still largely overlapping.

382   Three samples were selected for the UL-D4 bed, a carbonate-rich horizon located 25 m

383 abs (see Fig. 2): UL-D4a, from prismatic layers of an oyster; UL-D4b, from a barnacle

384 sheath; UL-D4c, the bulk sediment cemented within the same barnacle shell (Table 1). The

385 bulk sample, UL-D4c, exhibits a relatively low $^{87}Sr/^{86}Sr$ value and, consequently, a relatively

386 older age value, indicating that diagenesis had an ageing effect on the shells also in this bed.

387 Unfortunately, the $^{87}Sr/^{86}Sr$ values of the two supposedly pristine samples from this level are

388 very different. Since both these samples passed the diagenetic screening, we have no clue for

389 discarding one of them and retaining the other. Therefore, we decided to discard the samples

390 of the UL-D4 level from the age determination.

391   Finally, at 30 m abs, we took two samples (UJA-2a and UJA-2b) from different layers of a

392 single oyster shell, collected from key bed B of Di Celma et al. (2018b). The mean $^{87}Sr/^{86}Sr$

393 value provides a preferred age of 18.30 Ma for the key bed B, with a maximum age of 18.60

394 Ma and a minimum age of 18.00 Ma, in agreement with the levels dated below (Table 3).

395   The $^{87}Sr/^{86}Sr$ ages calculated for each bed confirm a Burdigalian age for the Ct1 sequence

396 of the Chilcatay Formation and are concordant with the $^{39}Ar–^{40}Ar$ ages of the ash layers and

397 biostratigraphic assessment of the studied Chilcatay outcrops. The time resolution of the SIS

398 method is not sufficient to discriminate the age of these closely spaced horizons. However,

399 the preferred ages of the sampled levels tend to be younger according to the stratigraphy

400 (except, as reported above, for the UL-D4 bed).

401

402 *5.3. Strontium Isotope Stratigraphy of the P0 sequence*

403 Carbonates from the P0 sequence are poorly preserved, resulting in just five samples from

404 a ~10 m-thick stratigraphic section located north of Cerro Submarino. Given the scarcity of

405 suitable carbonate samples, we also collected samples from well-preserved shark teeth

406 (phosphates). They show $^{87}Sr/^{86}Sr$ values that are consistent with those of the pristine

407 carbonate samples (see Fig. 6, Table 2). Taking also into account the limited thickness of the

408 P0 deposits exposed at Cerro Submarino, e we considered all the collected samples as

409 belonging to a single level and we calculated a unique $^{87}Sr/^{86}Sr$ age starting from five

410 different samples.

411 Three shark teeth were chosen from the lower portion of the P0 sequence, a few meters

412 above the PE0.0 unconformity, in the plain northward of Cerro Submarino (see Fig. 2). Of

413 the analyzed teeth, Tooth 1 is a lower anterolateral tooth of *Cosmopolitodus hastalis*, Tooth 2

414 is an upper tooth of the same species (Fig. 3D), and Tooth 3 is a lower tooth of *Isurus*

415 *oxyrinchus* (see Table 1). The three resulting $^{87}Sr/^{86}Sr$ values are slightly different from each

416 other, but there are no reasons to prefer one tooth over another and all these samples were

417 selected for the final age calculation.

418 A few meters above the PE0.0 unconformity, a calcite nodule from within a baleen whale

419 mandible (SUB-2, Table 1) was first selected following the hypothesis of precipitation during

420 early diagenesis, similarly to what hypothesized for the dolomite nodules found inside bone

421 cavities in the Pisco Formation (Gariboldi et al., 2015; Gioncada et al., 2016). However,

422 SUB-2 has a very low $^{87}Sr/^{86}Sr$ value similar to the late diagenetic cements, suggesting a late

423 diagenetic imprint of this nodule, and therefore it was discarded. Close to this sample, an

424 oyster was collected (SUB-5, Fig. 2), and the thin nacre layers were drilled, giving an

425 $^{87}Sr/^{86}Sr$ value similar to those of the shark teeth. Finally, a few meters above, three samples

426 were selected from level SUB-8bis (see Fig. 2): one from the presumably pristinely preserved

427 sheath of a barnacle (SUB-8bis1), one from the bulk sediment cemented inside the same

428 barnacle shell (SUB-8bis2), and the last one from a completely recrystallized shell of a

429 bivalve (SUB-8bis3) (Table 1). The samples from the bulk and the recrystallized bivalve

430 indicate that, as in the Ct1 sequence, diagenesis resulted in a substantial reduction of the

431 $^{87}Sr/^{86}Sr$ value and a consequent increase of the calculated ages. In turn, the pristine calcite of

432 the barnacle sheath shows an $^{87}Sr/^{86}Sr$ value similar to the other pristine samples and was

433 considered for the final age calculation.

434   Discarding samples affected by diagenesis, a mean $^{87}Sr/^{86}Sr$ value can be calculated

435 starting from 5 samples collected from the lower part of the P0 sequence. Together, the three

436 shark teeth, SUB-5, and SUB8bis1 result in a mean age of 13.45 Ma, with an uncertainty time

437 range spanning between 14.80 and 12.45 Ma. Consequently, by means of SIS, the P0

438 sequence can be placed in the Langhian–Serravallian (Table 3). The age of the P0 sequence is

439 now resolved, but poorly constrained because of the scarcity of well-preserved specimens

440 (allowing for just a few dated samples) and the intrinsic limits of the SIS method.

441

442 **6. Discussion**

443 *6.1. SIS age of the P0 strata*

444   Strontium data confirm a Burdigalian age for the Ct1 sequence of the Chilcatay

445 Formation, in line with the $^{39}Ar–^{40}Ar$ dating on tephra and with the biostratigraphic results

446 given by diatoms and silicoflagellates from the localities of Roca Negra and Ullujaya (Belia

447 and Nick, 2016; Di Celma et al., 2018b; Bosio et al. in press). In addition, they are consistent

448 in themselves, with stratigraphically lower beds yielding older or at least matching ages,

449 although this observation is limited by the broadly overlapping error ranges for each layer.

450 Overall, the consistency of the strontium dates from the Ct1 sequence confirms the suitability

451 of the method for dating sediments in the East Pisco Basin.

452   Our results also provide the first direct evidence for the age of the P0 sequence of the

453   Pisco Formation in the study area, placing this unit in the middle Miocene (Langhian–

454   Serravallian). This estimate is again consistent with the broad age constraints (ca. 9.5–18.0

455   Ma) imposed by radiometric dating and biostratigraphy (Di Celma et al., 2018b; Bosio et al.,

456   in press).

457   Current knowledge about both invertebrate and vertebrate assemblages of the P0 sequence

458   is poorly informative in terms of chronostratigraphy; that said, a middle Miocene age matches

459   the general aspect of the P0 oryctocoenosis. Indeed, mollusks suggest similarities with the

460   lower–middle Miocene Navidad Formation of central Chile (DeVries and Frassinetti, 2003).

461   Likewise, the baleen whale assemblage appears remarkably more archaic than that of the

462   overlying P1 and P2 sequences (Di Celma et al., 2017; Marx et al., 2017b), with the presence

463   of *Pelocetus* sp. (Bianucci et al., 2019) matching other early–middle Miocene occurrences of

464   this genus from Japan (Kimura et al., 2007) and eastern North America (Kellogg, 1965). Also

465   notable is the abrupt increase in baleen whale abundance relative to the underlying Chilcatay

466   Formation (Bianucci et al., 2018b), which appears to reflect a global early–middle Miocene

467   pattern (Marx et al., 2019). Sharks and rays are of limited utility, as all the taxa recognized so

468   far exhibit a stratigraphic range which spans for most of the Miocene at least. As a

469   consequence, all the elasmobranch taxa recognized from the P0 sequence but *Carcharocles*

470   *megalodon* and *Hemipristis serra,* are known from both the lower Miocene Chilcatay strata

471   exposed in the Ullujaya-Zamaca areas (Bianucci et al., 2018b; Di Celma et al, 2018, 2019;

472   Landini et al., 2019) and the upper Miocene Pisco strata (P1 and P2 sequences) exposed at

473   Cerro Colorado (Di Celma et al., 2017; Landini et al., 2017a, b). *Carcharocles megalodon,*

474   whose fossil record starts with the Burdigalian (Carrillo-Briceño et al., 2019, but see also

475   Perez et al., 2019, at this regard)*,* is well-known from the P1 and P2 beds but absent from the

476   Chilcatay Formation, where the genus *Carcharocles* is represented by the more archaic

477 species *C. chubutensis*. Conversely, *Hemipristis serra* is present in the Burdigalian deposits

478 of the Chilcatay Formation, whereas it is absent from the younger P1 and P2 sequences,

479 although it is known from outside the East Pisco Basin in deposits as young as the early

480 Pleistocene (Ebersole et al., 2017).

481

482 *6.2. Paleoclimatic implications*

483   Previous investigations on the invertebrate assemblages from the P0 and P1 sequences

484 revealed a marked faunal change coincident with the PE0.1 unconformity (Di Celma et al.,

485 2017). Specifically, species such as *Ficus distans* and *Miltha* cf. *vidali*, which also occur in

486 the Chilcatay Formation, associate P0 with the Navidad Formation of Chile, rather than the

487 Panamic fauna (DeVries, 2002, 2007; DeVries and Frassinetti, 2003). According to Nielsen

488 and Glodny (2009), an interpretation of the mollusk assemblage from the Navidad Formation

489 in the light of the ecological preference of extant genera suggests water temperatures of at

490 least 20°C for the Navidad area (34°S) during the early-middle Miocene. Indeed, the presence

491 in the P0 sequence of warm-water or tropical taxa such as Architectonicidae and Cypraeidae

492 (see Fig. 7A–C, H–J), as well as the occurrence of *Ficus*, indicates a warm-water, tropical

493 paleoenvironment for this unit. This is also supported by the finding of the only coral colony

494 ever collected from the East Pisco Basin, belonging to the family Rhizangiidae (Fig. 7F, G).

495 Rhizangiid scleractinians are the most common corals in shallow-water tropical and warm

496 temperate environments of the eastern Pacific (Cairns et al., 2005); in particular, the P0

497 specimens appear as morphologically close to the Miocene to Holocene genus *Culicia*, which

498 currently lives in the tropical waters of the Indo-Pacific region. On the whole, these

499 observations support the paleoclimatic reconstruction proposed by DeVries and Frassinetti

500 (2003), who hypothesized warm-water conditions for the southern Peruvian coast during the

early and middle Miocene, in contrast with the cooler conditions during the late Miocene and

early Pliocene.

Our data on the composition of the vertebrate oryctocoenosis from P0 also indicate

tropical to subtropical thermal affinities for the paleoenvironment testified by the sandy strata

that comprise the P0 sequence. In particular, among the recognized taxa, the knifetooth

sawfish *Anoxypristis* is currently known as a nectobenthic organism that inhabits coastal and

estuarine warm-water environments (e.g., D'Anastasi, 2013). Similarly, the extinct

snaggletooth shark *Hemipristis serra* (Fig. 7D, E) is one of the most common chondrichthyan

taxa in low-latitude neritic deposits of the Neogene, and its closest extant relative

(*Hemipristis elongata*) is known as a tropical nearshore shark that inhabits coastal waters not

deeper than about 30 m (e.g., Compagno, 1984). Interestingly, there are no late Miocene

occurrences of *H. serra* from the East Pisco Basin, even though this species persisted till the

early Pleistocene in many tropical/subtropical chondrichthyan assemblages worldwide, and

has even been recorded from the late Miocene strata of the Miramar Formation of northern

Peru (Apolín et al., 2004). A warm, tropical paleoenvironment sets P0 apart from the

remainder of the Pisco Formation, which is thought to reflect a cooler setting marked by

strong coastal upwelling (Dunbar et al. 1990; Di Celma et al. 2017). Overall, this pattern is

suggestive of late Miocene cooling along the Peruvian coast (DeVries and Frassinetti, 2003),

and therefore likely a strengthening of the Humboldt Current. This change might also explain

the local disappearance of *H. serra*, whose range likely contracted northwards as colder

conditions took hold along the coasts of southern Peru.

7. Conclusions

Along the western side of the Ica River (Peru), the age of deposition of the P0 sequence, the

lowest stratigraphic unit of the Pisco Formation, was an uncertain and debated issue. In the

526 present study, Strontium Isotope Stratigraphy was applied on carbonates and phosphates of

527 both the Chilcatay and Pisco formations for resolving the age of this paleontologically

528 significant unit.

529   In order to obtain reliable ages, not offset by diagenetic effects, samples were screened by

530 means of optical and scanning electron microscopy, cathodoluminescence, and ICP-OES

531 analyses, and only the best-preserved specimens were selected for the subsequent Sr analyses.

532   In this work, we provide new Burdigalian ages (18.8–18.0 Ma) for the Ct1 sequence of the

533 Chilcatay Formation and propose a Langhian–Serravallian age (14.8–12.4 Ma) for the P0

534 sequence of the Pisco Formation. This estimate is consistent with the relatively archaic aspect

535 of the fossil assemblage from the lower Pisco strata, and provides a time constraint for a

536 marked faunal change occurring across the PE0.1 unconformity. With respect to the

537 Chilcatay Formation, the obtained Sr ages perfectly agree with previous ^{39}Ar–^{40}Ar ages on

538 tephra layers and biostratigraphic results, confirming the feasibility of SIS in the studied

539 deposits. This gives further reliability to the middle Miocene ages obtained by means of Sr

540 isotope analyses for the P0 sequence.

541   Not least, both the invertebrate and vertebrate fossil assemblages indicate that the P0

542 sequence was deposited in a warm-water environment resembling that of the Chilcatay

543 Formation, but contrasting with the cooler and more productive setting of the P1 and P2

544 sequences. We suggest that the marked cooling distinguishing P0 from the remainder of the

545 Pisco Formation may reflect a middle–late Miocene strengthening of the Humboldt Current.

Figure captions

Figure 1. A. Map of the major Cenozoic sedimentary basins along the Peruvian coast. Major

structural highs are the Coastal Batholith, the Outer Shelf High and the Upper Slope Ridge.

The red dashed rectangle outlines location of the area shown in detail in panel B. Redrawn

and modified from Travis et al. (1976) and Thornburg and Kulm (1981). **B.**

Paleoenvironmental reconstruction of the Peruvian coast during the Miocene. Islands are

hypothesized on the basis of the distribution of the pre-Cenozoic rocks. Redrawn and

modified from DeVries and Schrader (1997).

Figure 2. A. Satellite image of the localities of Cerro Submarino, Ullujaya, and Roca Negra

along the western side of the Ica River (Ica desert). Based on a Google Earth image (© 2018

DigitalGlobe). **B.** Schematic stratigraphic sections measured at the Chilcatay outcrops of

Ullujaya (UL) and Roca Negra (RN) that show the stratigraphic position of the investigated

beds and the ^{39}Ar–^{40}Ar ages obtained from tephra layers. **C.** Field photo at Cerro Submarino,

with the location of the samples (blue stars) collected from the P0 sequence. The PE0.0 and

PE0.1 unconformities are traced in red.

Figure 3. A. Oyster shell from the PN Oyster level in the Ct1 sequence at Roca Negra. Note

the predation holes on the outer part of the shell. **B.** Pectinid specimen from the mollusk- and

barnacle-rich horizon in the Ct1 sequence at Ullujaya. Note the small drill holes and the

barnacle attachment scars (i.e., *Anellusichnus*). **C.** Barnacle plate from the Key bed C in the

Ct1 sequence at Ullujaya. Note the lamellar sheath (i.e., the thickened upper part of the inner

wall) from which the SIS samples were taken. **D.** Tooth of *Cosmopolitodus hastalis* from the

P0 sequence at Cerro Submarino.

855

Figure 4. A, B. Transmitted light and cathodoluminescence microscopical photo of a pectinid

shell. **C, D.** Transmitted light and cathodoluminescence microscopical photo of an oyster

prismatic layer with a low and homogeneous luminescence, punctuated by microborings with

a high luminescence. **E, F.** Transmitted light and catodoluminescence microscopical photo of

a poorly preserved oyster shell, characterized by an alternation of high luminescent layers of

sparry calcite. **G, H.** Transmitted light and catodoluminescence microscopical photo of the

transverse thin section of a barnacle shell showing tree-like interlaminate figures and the

parietal tubes filled by diagenetic calcite with a high luminescence.

864

Figure 5. A. SE (Secondary Electron) image of an oyster cross-section. Note the alternation

of different layers. **B.** Close-up of the oyster shell depicted in panel A. Note the alternation of

prismatic layers (light grey) and sparry calcite layers (dark grey). **C.** SE image of a well-

preserved prismatic layer of an oyster. **D.** SE image of a poorly preserved oyster shell

exhibiting dissolution features.

870

Figure 6. Diagenetic path diagrams, showing the major trends of diagenetic alteration. **A.**

Multi-component plot of $^{87}Sr/^{86}Sr$ ratio vs Sr concentration. **B.** Multi-component plot of

$^{87}Sr/^{86}Sr$ ratio vs Fe concentration. **C.** Multi-component plot of $^{87}Sr/^{86}Sr$ ratio vs Mn

concentration. **D.** Multi-component plot of Sr vs Mn concentrations. Arrows indicate trends

of diagenetic alteration.

876

Figure 7. Fossils of warm-water taxa from the P0 sequence. **A, B, C.** Cypraeid specimen in

lateral (A), dorsal (B), and apertural (C) views. **D, E.** Tooth of *Hemipristis serra* in lingual

(A) and labial (B) views. **F.** Rhizangiid corallites encrusting a cluster of barnacle shells. **G.**

880   Close-up of the corallites depicted in panel F. **H, I, J.** Architectonicid specimen in lateral (H),

881   dorsal (I), and ventral (J) views.

882

883   **Figure 8.** Schematic chronostratigraphic section of the Chilcatay (Ct1 and Ct2) and Pisco (P0

884   and P1) sequences according to Strontium Isotope Stratigraphy.

Table captions

Table 1. Sample list and description, with locality and stratigraphic data.

Table 2. Strontium isotope analysis results, reporting $^{87}Sr/^{86}Sr$ values and standard

deviations, with corrections based on the NIST NBS 987 and USGS EN-1 standards.

Table 3. $^{87}Sr/^{86}Sr$ ages for the Ct1 and P0 sequences, calculated from the LOWESS Table 5
(McArthur et al., 2012).
