Abstract

Between May 2009 and March 2010, six small scale paroxysms were recorded at Stromboli volcano (Aeolian Islands, Italy). The small scale paroxysm of 21 January 2010 was the only one characterized by a SSE to SW dispersal direction, which allowed access for sampling of the associated bomb-dominated deposit. The quenched marginal portions of twelve bombs were used to perform density, textural and chemical analyses to define the mechanisms operating in the shallow conduit during the explosion. Whole-rock density values span a range of 1100 to 2300 kg/m^3 which, using a dense rock equivalent density of 2850 kg/m^3, converts to a vesicularity of 20 to 61 %. The vesicle volume distribution (VVD) is unimodal, with a mode at 1.8 mm, consistent with a single bubble nucleation event followed by growth, coalescence expansion and/or densification. Crystallinity ranges from 30-62 vol. %. Vesicle and crystal contents, however, show considerable variation, consistent with the presence of an extremely dense and degassed component in the fragmented magma. Both groundmass

25 glasses and melt inclusions are chemically homogenous, with CaO/Al_2O_3 in the range 0.40-0.60. Melt

26 inclusion volatile contents (H_2O up to 0.47 wt%) are consistent with fragmentation of a shallow

27 magma residing at a depth of about 480 m. We suggest that dense, degassed and crystal-rich magma

28 formed a "soft" rheological plug at the top of the conduit. Under such a condition, bubbles can

29 accumulate under the plug to slowly build the pressure to a threshold point, after which the pressure

30 is enough to cause the fragmentation of the plug.

31 **Key words:** Strombolian explosions, conduit-capping plug, degassed bombs, melt inclusions, small

32 scale paroxysms

33

34 **1. Introduction**

35 Stromboli, a 924 m high volcanic island located in the Aeolian archipelago of the Southern

36 Tyrrhenian Sea (Fig. 1), is famous for its persistent state of activity that has been on-going since the

37 medieval period (Rosi et al., 2000). All explosive eruptions occur in the crater terrace at 750 m a.s.l,

38 where the three main active craters are located (Fig. 1) (Harris and Ripepe, 2007a). Normal explosive

39 eruptions at Stromboli have been long-used to define the Strombolian sub-type of explosive activity

40 and typically involve 10^2-10^3 kg of material (Harris et al., 2013) in repeated emissions of gas, bombs,

41 lapilli and ash in events that last a few to tens of seconds (Barberi et al., 1993; Rosi et al., 2013;

42 Houghton et al., 2016). Because of the variety of the ejected material associated with explosive

43 events, normal activity at Stromboli has been subdivided in four main groups: type 0 events are gas

44 jets carrying a very few small particles at high velocity (Leduc et al., 2015; Gaudin et al., 2017); type

45 1 events are dominated by emission of ballistic coarse particles; type 2a eruptions involve ash-rich

46 plumes with large numbers of ballistics, and type 2b events are characterized prevalently by ash

47 (Patrick et al., 2007; Harris et al., 2013). Volcanic activity at the Crater Terrace also involves

48 continuous degassing (Pering et al., 2016) and gas puffing (Ripepe et al., 1996; Harris and Ripepe,

49 2007a; Gaudin et al., 2017), as well as emission of lava flows (e.g. Calvari et al., 2008; Rosi et al.

50 2013). The explosive plumes associated with normal activity ascend to no more than 500 m, causing

51 a discontinuous deposit of lapilli, bombs and/or coarse ash within 50-400 m of the vent (Harris and

52 Ripepe, 2007a; Patrick et al., 2007; Rosi et al. 2013; Gurioli et al., 2014). This activity has typically

53 been associated with the bursting of large bubbles of gas at the surface of the magma column (Parfitt,

54 2004) to expel a mixture of gas loaded with particles (Bombrun et al., 2015). Thus, while Stromboli

55 itself has become synonymous with this mildly explosive, yet globally common, eruption style,

56 fragmentation conditions and shallow conduit dynamics at Stromboli have also become intimately

57 linked to those driving "Strombolian" activity.

58   Recently, the simple Strombolian eruption model whereby large slugs of gas ascend through

59 liquid resident in the conduit to burst at the surface (Jaupart and Vergniolle, 1989) has been

60 challenged due to the presence of ejecta with moderate-to-high crystallinity. While pyroclasts at

61 Stromboli have 40 to 55 vol% of crystals (Métrich et al., 2010; Gurioli et al. 2014), those at Etna have

62 >55 vol% (Polacci et al., 2006), and crystallinities of 30-40 vol% have been found at Yasur volcano,

63 Vanuatu (Métrich et al., 2011). These crystal contents create rheological conditions that are close to

64 the "eruptibility" limit for magmas (Marsh 1981). The presence of a highly viscous (10^5-10^6 Pa s),

65 crystal-rich magma has thus motivated the generation of new models to explain the passage of the

66 slug through a more complicated system of liquid and solids (Gurioli et al. 2014; Oppenheimer et al.,

67 2020). At Stromboli, Gurioli et al. (2014) described two quenched bombs where fresh magma was

68 mingled with batches of degassed, oxidized, microlite-rich and evolved magma with high viscosity

69 and crystallinity. They hypothesized that this stagnant and oxidized magma formed a rheological

70 layer at the top of the magmatic column through which the fresh magma burst. Textural modeling

71 and geophysical analysis confirmed that the presence of this high density, high viscosity magma layer

72 modulates the type of emission during normal activity (e.g. Lautze et al. 2005; Leduc et al. 2015;

73 Gaudin et al. 2017). This layer could be related to the presence of debris on top of the vent (Patrick

74 et al., 2007; Capponi et al., 2016) and/or the presence of a plug made up of cooled, degassed and

75 partially crystallized magma at the top of the column (Capponi et al., 2016; Del Bello et al., 2015;

76 Lautze and Houghton, 2007; Oppenheimer et al., 2020; Suckale et al., 2016).

Small and large scale paroxysms punctuate persistent activity at Stromboli on annual and decadal time scales (Rosi et al., 2013). Also termed "major explosions" (Barberi et al., 1993; Bertagnini et al., 1999; Harris and Ripepe, 2007b), small-scale paroxysms consist of events involving 10^4-10^5 kg of material, have a duration of around a minute (Gurioli et al., 2013), and are accompanied by short-lived plumes reaching a height of about 1 km (Rosi et al., 2013). They cause discontinuous ballistic fallout within a distance of 500 m (Gurioli et al., 2013), and ash fall to the coast (1.5 km distant) and beyond (Andronico and Pistolesi, 2010). Large scale paroxysms (Rosi et al., 2013) involve 10^6-10^7 kg of material (Rosi et al., 2006) and are the most powerful eruptive events recorded historically at Stromboli (Barberi et al., 1993; Bertagnini et al., 2011). They last several minutes and can send meter-sized bombs and blocks up to 2 km from the craters, with the concurrent formation of a convective plume that can ascend several kilometers (up to 10 km) above the vents (Pistolesi et al., 2008; Rosi et al., 2013). These larger events have been explained as having a deeper trigger than normal explosions. Eruptive dynamics during paroxysms is believed to be controlled by ascent of a deep-seated, volatile-rich, magma that mingles with a degassed magma residing in the shallow reservoir (Métrich et al., 2010).

Although spanning five orders of magnitude in terms of erupted mass, the small and large scale paroxysms appear to be associated with the same near-surface conduit dynamics as normal explosions, where the point of fragmentation is just a few 10's to 100's of meters below the vent (Ripepe and Harris, 2008). For some small scale paroxysms, partial plug obstruction has been observed and invoked as a trigger mechanism (Calvari et al., 2012). Calvari et al. (2014) also suggested that, between 2007 and 2012, the geometry of the upper portion of the system evolved by developing into a wide collapse depression that consumed the uppermost conduit, and which then became refilled by partially melted hot debris and scoria (Del Moro et al., 2013). These structural changes modified the shallow feeder conduit allowing a greater volume of magma to be stored and degas at quasi equilibrium conditions, a volume which stays hotter for longer, enhancing the

102 possibility for the degassed magma to mingle with the deep-seated magma and increase the number

103 of small scale paroxysms (Calvari et al. 2014).

104 Within this framework of current understanding of Strombolian activity, we present results

105 from an interdisciplinary study in which we are able to texturally and chemically characterize the

106 magma sitting at the top of the shallow conduit at Stromboli, as emitted during a small scale paroxysm

107 that occurred on 21 January 2010. Our aim is to investigate the possible role of this magma in the

108 formation of a plug during more energetic Strombolian (small scale paroxysms) eruptions. The work

109 is based on complete mapping of an entire bomb-field associated with a small scale paroxysmal tied

110 to detailed sampled to generate a unique data set of bombs, collected for the first time from a single

111 bomb field emitted during a small scale paroxysm at Stromboli. We show that these bombs represent

112 a window into the character of Stromboli's conduit allowing us to define the nature of the shallow

113 magma associated with small scale paroxysms. We find that, for the small scale paroxysm sampled

114 here, a dense and crystal-rich plug at the top of the conduit controlled the eruption style, a finding

115 which links the genesis of small scale paroxysmal Strombolian explosions to that of normal activity.

116

117 **2. Stromboli magmatic system and textural features**

118 Stromboli volcano exhibits a wide range of explosive styles which reflect differences in the

119 magma involved. Normal activity and effusive events are fed by a crystal-rich and volatile-poor high

120 porphyritic (HP) magma (Bertagnini et al., 2008, 1999; Francalanci et al., 2004, 1999; Landi et al.,

121 2008; Métrich et al., 2010, 2001). HP magma contains 45-55 vol% of plagioclase (0.1-2.5 mm),

122 clinopyroxene (0.5-5 mm) and olivine (0.1-4 mm) in equilibrium with a shoshonitic residual melt

123 (~52 wt % SiO_2 and ~4.5 wt% K_2O). This magma is emitted as black scoriae. Different textural facies

124 have been described for HP scoriae associated with normal activity (Andronico et al., 2008; Belien

125 et al., 2010; Colò et al., 2010; Gurioli et al., 2014; Lautze and Houghton, 2008, 2007, 2005; Leduc et

126 al., 2015; Polacci et al., 2006) and a review of all published data is given in Table C1.

127   During large, as well as in some small scale paroxysms, in addition to HP magma, a crystal-

128   poor and volatile-rich melt is erupted, this being low porphyritic magma (LP, Table C1) (Bertagnini

129   et al., 2008, 1999; Francalanci et al., 2004, 1999; Métrich et al., 2010, 2001; Pioli et al., 2014). LP

130   magma is rarely released as pure "golden pumice" even in ash and fine lapilli size and is often variably

131   mingled with the HP magma (Pioli et al. 2014). LP magma contains the same mineral phases present

132   in HP scoriae, although plagioclase is lacking as phenocrysts. Crystallinity is also lower (<5 vol%)

133   in respect to the black scoria, and the LP groundmass glass has a basaltic composition (~48 wt %

134   SiO_2 and ~2.5 wt% K_2O) (Bertagnini et al., 1999; Francalanci et al., 2004; Rosi et al., 2013).

135   Stromboli's plumbing system has become envisioned as a polybaric multi-reservoir system

136   (Métrich et al., 2010; Pichavant et al., 2011; Pompilio et al., 2012), consisting of: (i) a shallower

137   reservoir (~2 km) where the HP magma resides, (ii) a deep ponding zone at 7-10 km occupied by LP

138   magma, and (iii) a complex transition zone between the two, possibly characterized by a crystal mush

139   zone periodically influenced by ascending LP magma (Francalanci et al., 2004, 1999; ; Métrich et al.,

140   2010). With this in mind, the HP magma most likely derives from LP magma through crystallization

141   driven by decompression and water exsolution at low pressure (Métrich et al. 2001).

142

143   **3. The small scale paroxysm of 21 January 2010**

144

145   At 20:45:03 (local time) on 21 January 2010, thermal, infrasonic and seismic sensors of the University

146   of Florence (Italy) recorded a strong explosion at Stromboli. This small scale paroxysm lasted 51

147   seconds, consisted of three main phases, and was described in detail by Gurioli et al. (2013). The

148   explosion occurred after few days of crater inactivity. Following the reconstruction of Gurioli et al.

149   (2013), Phase 1 comprised two simultaneous bursts which sent bombs to the S/SSE and SW. Each

150   burst comprised two components: a leading spray of smaller bombs quickly followed by emission of

151   larger bombs that attained lower heights and fell closer to the vent than those of the first burst. An

152   associated cloud of gas and scarce finer material was observed, mostly connected to the SW-directed

153   burst and directed at an angle of 45°. The second phase began after seven seconds and involved

154   emission of two or three plumes of gas and scarce fine particles, lacking bombs. Phase 2 was

155   effectively over within 20 seconds and was followed by a third phase marked by a series of weakening

156   gas-rich puffs that lasted 24 seconds. Bombs were characterized by launch velocities between 52 and

157   70 m/s and the total erupted bomb mass was 3.6×10^4 kg, with bomb mass emission rates being

158   around 2×10^4 kg s^{-1} (Gurioli et al., 2013). Fine fragments were indistinguishable and/or minimal

159   across the deposit (only one coarse lapilli was found), and sedimentation from phases 2 and 3

160   produced no distinguishable layer in more distal locations, as instead was observed for the small scale

161   paroxysm of 24 November 2009 (Andronico and Pistolesi, 2010).

162

163   **4. Sampling and analytical methods**

164

165   *4.1 Sample collection*

166   Samples studied in this work were mapped and collected during two sampling campaigns: one in June

167   2010 and another in June 2011 (6 and 18 months after the January 2010 eruption that emplaced the

168   sampled bombs). In total, 780 bombs were mapped (Fig. 1) and 55 bombs representative of the deposit

169   were sampled, in June 2010, along the longitudinal and horizontal dispersal axis (Fig.1, Gurioli et al.,

170   2013) every ten meters. As explained by Gurioli et al. (2013), the thermal video of the 21 January

171   event revealed bombs moving away from the camera, indicating a southward dispersal direction

172   opening at an angle of 180° (Fig. 1). Within this expected landing distribution, we mapped the SSE-

173   and the SW-directed bursts (Fig. 1). This means that the small scale paroxysm of 21 January 2010

174   was the source of the bombs, because it was the only explosion of the series of six small scale

175   paroxysms events that occurred between May 2009 and May 2010 with such a dispersal direction.

176   This distribution was confirmed by checking of thermal video for all six small scale paroxysms that

177   occurred during 2009-2010 (cf. Table 1 of Gurioli et al., 2013). The bomb field of 24 November 2009

178   had a southeast dispersion axis (Andronico and Pistolesi, 2010). This field overlaps that of 21 January

179   2010 to the east, but the majority of these bombs (purple diamonds in Fig. 1) can be distinguished

180   based on their larger size and on photos taken before and after the 21 January 2010 explosion (see

181   Item DR1, in Gurioli et al. 2013). All measured and collected bombs from the January 2010 event

182   were fresh, glassy and iridescent, and stratigraphically above older pyroclasts—a characteristic that,

183   even after 18 months, allowed them to be easily distinguished. Furthermore, all bombs were

184   photographed, measured (for long and short axis) and GPS-located during the June 2010 campaign,

185   allowing them to be relocated with confidence during the June 2011 campaign, when the dispersion

186   map was better defined and further morphological measurements of the bombs were made.

187

188   *4.2 Density and textural measurements*

189   For the 55 bombs sampled by Gurioli et al. (2013), densities were measured both as bulk density of

190   the entire bomb (Figs. 2A-F and Table C3 in Appendix C) and as density of the marginal portion of

191   the bomb (including quenched rind and some portion of the bomb, see limits of the thin section areas

192   Figs. A1 to A6 in Appendix A). Density was measured by comparing the sample weight in water with

193   the sample weight in air. While bomb rinds were made impermeable using Parafilm^{TM} wax, bulk

194   bomb (which were larger than 8-10 cm) density measurements were carried out following the "natural

195   waterproofing" strategy (Gurioli et al., 2015). We measured the weight of the bombs in water using

196   the apparatus of Fig. 2G. The quenched rind prevented the water from entering the interior, as

197   confirmed by the lack of bubble formation in the water and the constant weight of the bomb before

198   and after immersion. After these measurements, bombs were cut into two slices along the major axis

199   and thin sections prepared from the marginal portions of 12 samples. Vesicularity (Φ) was determined

200   using the dense rock equivalent (DRE) density of 2850 kg/m^3, as measured by Pistolesi et al. (2011).

201   Textural measurements, both for vesicles and crystals, were performed on 12 bombs following

202   the technique of Leduc et al. (2015). Images of sliced bombs and thin sections were acquired using a

203   desktop scanner, while the JEOL JSM-5910LV scanning electron microscope (SEM) at Laboratorie

204   Magmas et Volcans (LMV) in Clermont-Ferrand (France) was used for larger magnification images.

205   Each image was adjusted in Adobe Photoshop (e.g., broken bubble walls were connected) and

206   processed using the Fast Object Acquisition and Measurement System (FOAMS) software of Shea et

207   al. (2010). From each image, vesicles (black), crystals (white) and glass (gray) were extracted (Fig.

208   B1, Appendix B). Percentage of vesicles and crystals were then measured (Table 1) and vesicle

209   volume plots created (Fig. B2). Our CSD plots represent the distribution of all mineral species: we

210   assumed that plagioclase crystals dominate the microphenocrysts and microlites range, while

211   clinopyroxene and olivine crystals rule the phenocrysts population (see Figure B5).

212

213   *4.3 Geochemical analysis*

214   Chemical analysis of groundmass glasses, phenocrysts and melt inclusions (MI) were carried out

215   using the Philips XL30 SEM at the Dipartimento di Scienze della Terra (DST, Università di Pisa,

216   Italy) integrated with an energy-dispersive X-ray spectroscopy (EDS) which employs the EDAX-

217   DX4 software. Operating conditions were a 20 kV voltage and a 0.1 nA beam current. A raster area

218   of 100 μm^2 was employed for glass analysis to reduce light element loss. A set of reference standard

219   of natural trachytic (CFA47), basaltic (ALV981R23) and pantelleritic (KE12) glasses was analyzed

220   before each session. Major element composition of the groundmass glasses was analyzed using the

221   electron microprobe (EMP), SX-100 CAMECA, at LMV. Operating conditions were an accelerating

222   voltage of 15 kV and a defocused beam with an 8 nA current intensity. A comparison between EDS

223   and EMPA analysis is reported in Table C5.

224   Phenocrysts were hand-picked, mounted on slides and double polished. After petrographic

225   inspection, selected melt inclusions were prepared for volatile measurements. H_2O and CO_2 were

226   analyzed by transmission IR spectroscopy (FTIR) using a Nicolet iN10 equipped with a high-intensity

227   EverGlo IR source and a MCT-A detector cooled with liquid nitrogen at DST. Concentrations were

228   calculated according to the Beer-Lambert law: $C = Abs \times PM / \varepsilon \times \rho \times d$, where Abs is the absorbance,

229   PM the molar mass (g/mol), ε the molar absorptivity (L/mol-cm), ρ the MI density (kg/m^3) and d the

230   MI's thickness (cm). Melt density was calculated by major element composition (average 2630

231 kg/m^3) and thickness of each sample was measured using a calibrated optical microscope. All the

232 measured and calculated Beer-Lambert parameters are given in table C2.

233

234 **5. Results**

235

236 *5.1 Macroscopic description and density analysis*

237 All sampled bombs are uniformly black with dimensions ranging from 5 to 44 cm, the smallest clast

238 being the only coarse lapilli found and sampled across the bomb field (Figs. 2A to 2E and Figs. A1

239 to A6,). Most have a quenched rind (Figs. 2B, 2D and 2E) of variable thickness (4-18 mm) which is

240 rich in crystals and small vesicles (e.g. S20 in Fig. A1 and A7 in Fig. A5,), while slightly larger

241 vesicles are normally clustered, more or less homogeneously, in the interior of the bomb (Fig. 2).

242 Occasionally, the central portion of the bomb is characterized by a large, centimetric void (Fig. 2E).

243 The occurrence of this difference between the marginal portion and the center is more marked for the

244 highly vesicular samples, while some of the densest bombs lack such a difference (Fig. 2 and Figs

245 A1 to A6,). However, even in the vesiculated samples, poorly-vesiculated areas are scattered across

246 the whole bomb surface. All bombs are scoriaceous apart from one (Fig. 3A), which contains an

247 elongated, light toned, vesicle-rich and crystal-poor pumice zone, typical of LP magma. The contact

248 between the pumiceous and scoriaceous zone is sharp and well-defined near the bomb's outer edge,

249 but irregular towards the interior (Fig. 3A).

250 Densities for all of the 55 samples have a Gaussian trend, with density values in the range of

251 1100 to 2300 kg/m^3 (Fig. 2F and Table C3). Similarly, the marginal portion samples (the cut for the

252 thin sections) record narrower density range (1140-2050 kg/m^3). Density values for the marginal

253 portion are always lower than the correspondent values for the whole bombs (Table 1).

254

255

256 *5.2 Textural data*

257 For the twelve analyzed bombs, porosity decreases as the number of large, coalesced, centimetric to

258 millimetric vesicles decreases (Table 1 and A1-A6; Figs. 4D, 4E and 4F). In contrast, the number of

259 small vesicles (<50 μm in diameter), which are typically rounded (Fig. 4E), increases as bomb density

260 increases. The LP facies differs from the HP facies within the same scoria sample, mostly because of

261 its very high vesicularity, with a population of rounded, small to medium sized vesicles that are

262 normally organized in chains (Fig. 4C).

263 The simplest vesicle volume distribution histograms (VVDs, Fig. 5A-D) display unimodal,

264 symmetrical distributions, with vesicles ranging from 0.03 to 18 mm and a mode value at around 1.8

265 mm. More complex VVD histograms are characterized by negative or positive asymmetrical

266 distributions with the same modes at 1.8 mm or finer modes at 1.3 or 0.7 mm (Fig. B2). Only for

267 A23, S20 and S28 a bimodal distributions is present due to a second coarse population around modes

268 of 4, 7 or 17 mm (Fig. B2). VVDs for whole bombs (in black in Figs. 5A-C and B2) and marginal

269 portions (in grey in Figs. 5A-C and B2) are very similar, although the marginal portions are always

270 more vesicular than the corresponding whole bomb. Only the LP texture (Fig. 5D) is different, having

271 a much greater vesicularity (67 %) and a unimodal, symmetrical distribution. This latter distribution

272 is due to the lack of large vesicles and abundance of small vesicles with a main mode at around 0.5

273 mm (Fig. 3C and Fig. 5D). In agreement with Polacci et al. (2009, 2006) and Cigolini et al. (2008),

274 corrected vesicle number density (N_v^{corr}) values are of the order of magnitude of 10^2 and 10^3 mm^{-3},

275 with the LP texture having the greatest value (Table 1). Some of the densest scoria also have relatively

276 high values of N_v^{corr} due to an increase of small vesicles in respect to the more porous scoria (Fig. 4

277 and Table 1).

278 Bombs have a crystal assemblage that comprises plagioclase, clinopyroxene and olivine (Fig.

279 4A) in a uniform glassy groundmass (Fig. 4B). Also in agreement with Cigolini et al. (2008) and Pioli

280 et al. (2014), crystallinity corrected for vesicularity ranges from 30 to 63 vol. % for the scoria, but for

281 the LP texture the crystal content is just 1.7 vol. %, (Table 1). Crystallinity is correlated with

282 vesicularity, with the least dense bombs having the highest crystal contents (Table 1). The whole

283 CSDs are very similar among all samples (Fig. 5E and Fig. B3-B4), where crystal sizes range from

284 50 μm to 14 mm. The CSD curves can be divided into three portions defined by different slopes.

285 Based on the whole CSD population size (Fig. 5G-H and B3-B4), we defined phenocrysts as crystals

286 with long axes of more than 350 μm, microphenocrysts with long axes between 100 and 350 μm, and

287 microlites with long axes less than 100 μm; where microlites and microphenocrystals are mostly

288 formed by plagioclase.

289

290 *5.3 Groundmass glass and mineral chemistry*

291 At the microscale (thin section), the groundmass glass of scoriae appears dark or light brown,

292 although different colors do not correspond to differences in chemical composition, as already proved

293 by Leduc et al. (2015). The chemical homogeneity of the glass is apparent in the major element oxide

294 frequency diagrams (Figs. 6 and 8A-B). The glass is basaltic trachyandesite ($SiO_2 \sim 53$ wt% and

295 $CaO/Al_2O_3 \sim 0.49$) with a shoshonitic character ($K_2O > 4$ wt%) and its SiO_2 content overlaps the bulk

296 rock composition (Fig. 6B). Pumice glass is trachybasaltic in composition ($SiO_2 \sim 49$ wt% and

297 $CaO/Al_2O_3 \sim 0.61$) and is distinguishable from scoria glass for MgO, FeO, TiO_2, Al_2O_3 and K_2O

298 contents (Figs. 3B and 6). The groundmass glass has a maximum H_2O content of 1600 ppm. The bulk

299 rock composition of the bombs falls in the trachybasalt field (white star in Fig. 6A).

300 Plagioclase crystals show both homogeneous and zoned textures and they are in the range

301 An_{61} - An_{83}. Zoned plagioclases have sieved texture zones, with an An-rich cores (An_{83}) surrounded

302 by labradoritic rims. Unzoned plagioclases are in the range An_{61-70}. Pyroxene phenocrysts, normally

303 zoned, have diopsitic/augitic compositions, being in the range $Mg\#_{73-89}$. Olivine crystals are

304 homogeneous and exhibit a narrow compositional range (Fo_{70-73}).

305

306 *5.4 Melt inclusions: petrography, major element and volatile composition*

307 Naturally-quenched, light brown, melt inclusions are widespread in plagioclase, olivine and

308 clinopyroxene crystals (Fig. 7). Plagioclase crystals contain small MIs which have been neglected in

309 our study due to their small size. Olivine and clinopyroxene crystals contain both small-sized (10-20

310 μm) and large-sized (>100 μm) MIs. The latter are mostly found in olivine crystals and they are

311 usually glassy without significant petrographic evidence of post-entrapment crystallization (Fig. 7A).

312 However, diffusive re-equilibration of the inclusion with its host can modify the composition of the

313 trapped melt, along with crystallization of olivine on the walls of the inclusion. Therefore, we

314 corrected olivine-hosted MI compositions for post-entrapment processes (PEP) using Petrolog 3.0.

315 Olivine-hosted MIs required PEP correction between 0-5%. Clinopyroxene-hosted MIs needed up to

316 16% post-entrapment dissolution of the host mineral back into the inclusion (Table C4). A selection

317 of raw and PEP-corrected MI compositions is reported in table C4. PEP-corrected MIs, which are

318 used in the subsequent discussion, are chemically homogenous and they exhibit a shoshonitic

319 character (Fig. 6), with a Na_2O+K_2O around 7.5 wt%, overlapping the groundmass field. Indeed,

320 frequency histograms of major oxides (Fig. 8) highlight similar compositions for both MIs and

321 groundmass glasses, showing a modal value of oxides (e.g. K_2O and FeO) centered at the same

322 percentage. H_2O in MI ranges from 0.27-0.47 wt % (Table 2), while CO_2 content is below the

323 detection limit.

324 All of our data highlight a homogeneous chemical composition, with MgO between 2.8 and

325 5.8 wt% and K_2O/Na_2O in the range 0.9-1.8 (Table 2), and fall within the HP glass field for normal

326 activity (Fig. 6B) (Leduc et al., 2015; Métrich et al., 2005; Pioli et al., 2014). Only the pumice

327 groundmass glass moves away from HP field (Fig. 3). A relation between MI and groundmass glass

328 both in HP (and LP) products is reported in Figure 6B, as a CaO/Al_2O_3 vs K_2O diagram. MIs show a

329 CaO/Al_2O_3 ratio around 0.40-0.60 and they plot in a field far away from MI from pumice of Pioli et

330 al. (2014) and Métrich et al. (2001; 2005). MIs, found in pumice clasts, display more primitive

331 features and they have a wide range of CaO/Al_2O_3, this being from 0.5 to up 1.0 (Fig. 6B).

332 Scoria bulk-rock chemistry is comparable with the pumice groundmass glass (Fig. 6), whereas

333 the scoriae groundmass can be derived from the whole rock composition by crystallizing ~55 wt%

334 plagioclase, clinopyroxene and olivine (Métrich et al., 2001), in accordance with our textural analysis

335 (Table 1). All of these points suggest that the trapped melt (i.e. MIs) can be assumed as representative

336 of the melt present in the conduit just before the explosion. Therefore, the volatile (H_2O and CO_2)

337 content can be used to infer the depth of the melt in the conduit. Using VolatileCalc 2.0 (Newman

338 and Lowenstern, 2002), we have estimated a minimum volatile saturation pressure of 13.5 MPa. This

339 estimated pressure, assuming a magma DRE of 2850 kg/m^3 (Pistolesi et al., 2011), corresponds to a

340 depth of about 480 m.

341

342 **6. Discussion**

343

344 *6.1 Textural evidence for a degassed magma*

345 The marginal portions of the bombs have lower density values with respect to their parental bomb.

346 Usually this should be the inverse, because the external portions of a bomb should be quenched faster

347 than the internal portion and preserve a pristine texture where expansion and coalescence of vesicles

348 are impended. In contrast, vesiculation (in terms of expansion and/or coalescence) and sometimes

349 crystallization, in the bomb interior, continues after emission, so processes of post-deposition

350 modification are prevalent (e.g., Fig. 2E). Therefore, post-fragmentation expansion and formation of

351 blisters at the center of a bomb should reduce the density values for the whole bomb over those of the

352 quenched surface. In our sample collection, only a few bombs have large gas blisters (Figure 2E), but

353 those quantified in this study (see photos in Appendix A) are not as expanded as they should have

354 been because we are dealing with gas-depleted magma. Only in a few bombs can we see concentration

355 of large vesicles, but we see no real vesicle gradient (samples S27, S20, A25, A7). The lack of a any

356 obvious expansion gradient, the lack of large vesicles and the presence of scattered, less vesiculated

357 areas, causes the whole bomb to be denser than the area covered by the thin section. However, all

358 bombs, even those with central blisters, belong to the high density (HD) class described by Lautze

359 and Houghton (2005) and have densities comparable with the highest values found by Gurioli et al.

360 (2014) (Table C1). This means that these products are truly degassed, so that the internal vesicles

361   could not have expanded to any significant extent. Generally, at Stromboli, post fragmentation

362   expansion features are more predominant in the scoria lapilli grain size (which are slightly richer in

363   gas in respect to bombs), resulting in an increase in clast density as the size of the pyroclast increases

364   (see Fig. 1 in Bombrun et al. 2015).

365   Low density material was not found across the bomb field (Gurioli et al. 2013) and there was

366   no evidence of distal sedimentation of fine material, as observed by Andronico and Pistolesi (2010)

367   for a small scale paroxysm at Stromboli in 2009. The degassed nature of the magma is borne out by

368   MI data, which suggests the occurrence of a degassed magma residing in the shallow system.

369   However, this magma (Fig. 6B) is not as microlite-rich and is not as evolved as the magma found by

370   Gurioli et al (2014). As explained by Gurioli et al (2014), bombs sampled during normal activity

371   undergo cooling, crystallization and oxidation because sit at the very top of the magmatic column,

372   being a thin rind at the free surface and therefore representing a very thin crust at the head of the

373   degassing magma column. In the 2010 small scale paroxysm sampled here, we did not find the

374   equivalent of such a thin conduit-capping "crust". Based on our observations of the thermal video for

375   the 2010 event, we argue that this crust probably fell within 200 m of the vent where it was not

376   possible to sample. However, the degassed magma within the conduit, that was resident beneath the

377   cooling crust, was too hot to crystallize microlites or to undergo oxidation, although the zonation of

378   the plagioclase reveals a prolonged residence time within the shallow conduit (cf. Landi et al., 2004),

379   as does the reduction in vesicles in the high density products. This is also clear in Figure 2 where low

380   density bombs are associated with post-eruption vesicular gradients, which it is not the case for high-

381   density samples (Figs. 2b, 2d and 2e). These high-density bombs thus represent the physical

382   characteristics of the magma at the top of the column at the moment of the explosion.

383   VVDs are generally used to infer the condition of the bubbles in the magma at the time of

384   explosion if quenching is effective and post fragmentation can be excluded (Gurioli et al. 2018, 2015,

385   2014; Polacci et al. 2006). The single mode observed here is consistent with a single bubble nucleation

386   and growth event, while bimodal distributions have been observed only in the three samples having

387   the best evidenced of expansions and coalescence for the large vesicles. While large vesicles dominate

388   in relatively low-density bombs, small vesicles increase in number in the high-density products,

389   where coalescence is less visible. These features are consistent with Lautze et al. (2008, 2007, 2005)

390   and Gurioli et al. (2014) who found that the most outgassed material, which experiences a longer

391   residence time in the conduit relative to the traditional HP magma, was denser and lacked syn-

392   eruptive coalescence signatures. Following Belien et al. (2010), we can also ascribe the presence of

393   small-sized vesicles as being due to the influence of crystals. Crystal content is positively correlated

394   with the percentage of small-sized vesicles, where bubbles will deform and split during percolation

395   processes occurring in a steadily crystalizing mixture. All of these observations indicate that the

396   erupted bomb mass derived from a slowly degassing, crystallizing source sitting at the top of the

397   shallow system. Although emitted as part of a small scale paroxysm, the texture of the bombs suggests

398   a single stage of bubble nucleation and growth, typical of normal Strombolian activity (cf. Lautze and

399   Houghton, 2005; Polacci et al., 2006).

400   CSDs show similar relationships to those presented by Pioli et al. (2014). In Figure 5F we plot

401   CSD curves with the highest (black) and lowest (grey) crystallinities from Pioli et al. (2014),

402   Fornaciai et al. (2009) and this study. While normal activity samples (Fornaciai et al. 2009) show

403   linear trends, samples emitted during small scale paroxysms appear to correlate with crystallinity,

404   with low crystal frequencies at lower crystallinities, as also found by Pioli et al. (2014). Finally, the

405   small size interval of CSD curves can be affected by crystal fragmentation (Forien et al., 2011) which

406   would produce the observed exponential trends.

407

408   6.2 *Geochemical constraints and volatile-based estimates*

409   Our chemical data highlight the exclusive occurrence of a shoshonitic, chemically

410   homogeneous (HP) magma. Only the pumice groundmass glass moves away from the HP field and

411   its chemistry is consistent with a deep-seated LP magma as defined by Métrich et al. (2010). A

412   distinction between HP and LP glass is clearly shown in Figure 3B, where we report a geochemical

413 transect across the HP-LP-HP facies. The two melts are distinguishable especially at the edge between

414 the scoria and the pumice, where the LP glass has a more primitive signature. The observed gap

415 between the composition of pumice and of scoria glass, together with the element frequency diagrams

416 (Fig. 8), allow us to rule out mingling processes down to a micrometric scale. Therefore we interpret

417 the "golden pumice" as a xenolith that was present at the top of the magmatic column before the

418 explosion, which was emitted during an earlier event and then recycled by the sampled event. Many

419 bombs were also broken in the field and did not show evidence of LP portions. Nevertheless, the LP

420 magma presence cannot be totally excluded, as we could not sample the very scarce finer material

421 visible in the explosions. Evidence of LP magma in coarse ash from normal activity has already been

422 well documented by D'Oriano et al. (2011). Thus, this small scale paroxysm appears to have involved,

423 and been driven by, an entirely HP magma.

424   The low volatile content of our glasses is consistent with a magma that has been free to degas,

425 and which has thus lost almost all of its H_2O and CO_2. From MI investigations we can thus assume

426 that MIs were trapped inside the shallow portion of the conduit above a depth of 500 m. This depth

427 corresponds at the zone where very long period (VLP) signals have been located during normal

428 through paroxysmal activity at Stromboli (Chouet et al., 2003; Ripepe and Harris, 2008; Gurioli et

429 al., 2014), reinforcing the MI-based pressure calculation and increasing the strength of the argument

430 posed by our data. We note, here, that the depth of the VLP has not been linked to the thickness of

431 any degassed layers, but instead has been related to a level at which gas coalescence may occur

432 (Ripepe et al. 2001; Chouet et al. 2003), at which a specific conduit geometry exists that promotes a

433 change to a bubbly flow regime (James et al. 2009), or where the last crystallization may occur, as

434 shown in this paper. Instead, considering the total mass of the deposit of 3.6×10^4 kg (Gurioli et al.,

435 2013) and a mean bomb bulk density of 1850 kg/m^3, for a conduit diameter of 1 m (Vergniolle et al.,

436 1996), we can estimate the in-conduit thickness of the erupted, degassed HP magma to have been

437 approximately 25 m, in agreement with the length of the plug of 10-50 m estimated by Woitischek et

438 al. (2020). This would thus have contributed a 25 m thick layer at the head of a density-stratified

439 magma column above the VLP, with our data suggesting that crystallization is complete (or

440 completed) by the depth of the VLP.

441

442 *6.3 Implication for Strombolian eruptions*

443 The homogeneous nature of these bombs is in contrast with the hypothesis of a finger-like

444 system composed of a network of smaller volumes of different magma, as proposed in Calvari et al

445 (2014). In such a scenario we should have expected a more heterogeneous deposit with evidence of

446 non-juvenile materials stripped off from the explosion and mingling with the LP magma. The

447 presence of the LP magma involved as xenoliths can be consistent with a simpler, large storage

448 reservoir that allows more HP magma to accumulate and at the same time, preserve old magma left

449 behind by more energetic explosions.

450 Oppenheimer et al. (2020) investigated and modelled the physical interactions between

451 bubbles and crystals defining a "soft plug model" for Strombolian eruptions, in which large quantities

452 of crystals temporally impede and/or delay bubble ascent, with consequent bubble accumulation

453 under the plug increasing until the pressure exerted by this building accumulation becomes suddenly

454 released. The term "soft" is used for this kind of low-melt-viscosity plugs, that areequivalent to the

455 rheologically "stronger" plugs involved in Vulcanian-style eruptions (cf. Oppenheimer et al., 2020).

456 It is known that magma residing in the shallow conduit of Strombolian volcanoes are crystal rich,

457 with 30 to 60 vol%. This amount of crystals is responsible for the development of an effective yield

458 strength which favors bubble accumulation and subsequent local overpressure. We believe that the

459 21 January 2010 small scale paroxysm at Stromboli volcano is consistent with the fragmentation of

460 a dense and crystallized plug of magma residing in the upper part of the conduit. Fragmentation of

461 this 25 m thick plug resulted in the generation of a very coarse population of pyroclasts that ascended

462 the conduit and fed the resulting plume.

463 Our study thus shows that a "soft" plug control exists for Strombolian explosions, where

464 eruptive events involve crystal-rich magmas which form strong and poorly-permeable plugs

(Oppenheimer et al., 2020) through which ascending slugs must burst during both normal and paroxysmal eruptions (cf. Gurioli et al., 2014). Possibly, for the small scale paroxysms, the change in geometry of the upper feeding systems could have favored the accumulation of a relatively large quantity of HP magma (Calvari et al. 2014). We here show that, in addition to the configuration of the flow within the conduit (Capponi et al., 2016; Del Bello et al., 2015; Oppenheimer et al., 2020; Suckale et al., 2016), the transition between different strombolian activity styles is controlled by the presence of a crystal-supported stagnant magma sitting at the top of the magma column. This suggests that a weak plug model is reasonable for "strombolian" systems characterized by moderate-to-high crystallinities, as also observed for other strombolian-type eruptions such at Yasur, Villarrica and Erebus volcano (Woitischek et al. 2020).

7. Conclusion

Recent work has shown that the shallow system at Stromboli is a highly dynamic environment (Calvari et al. 2014) that experiences a continual change in the character and rheology of the resident magma during normal explosive activity (D'Oriano et al., 2011; Lautze and Houghton, 2008, 2007; Leduc et al., 2015). In this model, a degassed layer with high viscosity and yield strength (Gurioli et al., 2014), or a "plug" (Calvari et al., 2012; Oppenheimer et al., 2020; Suckale et al., 2016), can form and decay (Leduc et al., 2015). Suckale et al. (2016) argued for the presence of a porous plug of HP magma beneath the entire crater terrace, made up of crystals, bubbles and melt, but with an overall solid-like behavior. In this interpretation, normal eruptions are connected to the tensile failure of the plug due to over-pressurization following build up, or arrival, of gas volumes at the base or within the plug; failure of the plug then feeds the eruption during normal events (Gurioli et al., 2014). Our data now indicate that some small scale paroxysms have a similar genesis, meaning that the model, and process, scales-up.

Large, and some of the small, paroxysmal events at Stromboli have typically been considered as associated with the ascent of deep-sourced LP magma (Andronico and Pistolesi, 2010; Cigolini et

al., 2015; Pistolesi et al., 2011). However, bombs sampled from the 21 January 2010 small scale paroxysm show that this is not the case. Indeed, we find that no LP magma was involved, and that the emission resulted from the fragmentation of a cap of degassed and dense HP magma. Thus, the capping model invoked for normal explosions at Stromboli can be scaled up to small scale paroxysms with a deformed flow regime (Oppenheimer et al., 2020) governing the ascent dynamic. In the case of the small scale paroxysm examined here, the higher magnitude and energy (and thus also distance reached by the bombs) is due to the formation of a plug when compared with normal explosions. The period of inactivity at the crater involved (a few days) probably allowed the plug to form a cold crust, obstructing the crater and promoting a larger explosion than normal. This finding strongly supports that we need to review our mechanical model for Strombolian eruptions and move away from simple foam collapse and bubble ascent speed models (e.g., Parfitt, 2004) in rheologically "clean" and simple conduits, and move towards more complex models (Del Bello et al., 2015; Oppenheimer et al., 2020) which consider strong rheological stratification effects due to near-surface crystallization processes. Our findings thus support a new model whereby shallow conduit dynamics control the magnitude, intensity and character of Strombolian explosions, even the more explosive events, where for all cases the effect of a degassed, crystallized cap must be considered.

533   Stromboli. A) Microscope image at polarized light showing the general mineral assemblage formed

534   by plagioclase, pyroxene and olivine. B) BSE image of the groundmass glass (light grey); in darker

535   grey are the plagioclase and in black the vesicles; C), BSE-SEM image of the vesicle-rich golden

536   pumice; D), E) and F) BSE images of scoria with different vesicularity.

Figure 5. Vesicle volume distributions (VVDs) and crystal size distribution (CSDs) for selected samples. (A-C) VVDs for three selected scoria samples and (D) for the golden pumice in sample A25. Each diagram is formed by a grey histogram (representative the texture of the marginal portions of the bombs) and a black histogram (representative the texture of the whole bomb). The golden pumice is in white and the distribution is characterized by a predominance of small-size vesicles. For each sample, we indicate the vesicularity of the whole bomb (Φ_{bomb}) and of the marginal portions (Φ_{quen}). (E) CSDs of all studied samples, in the crystal size interval 0-15mm. Single CSD curves are reported in appendix B3 and B4. (F) CSDs of samples with the highest and lowest crystallinity from this study and comparison with samples studied in Pioli et al. (2014) and Fornaciai et al. (2009). (G-H) CSD curves in a restricted crystal size range (0-1.4 mm), showing the three crystals families (gray lines), as microlites (<100µm), microphenocrystals (100-350 µm) and phenocrystals (>350 µm).

Figure 6. Scoria groundmass glass analyses (red circles) and olivine- and pyroxene-hosted melt inclusions (orange triangles) of scoria samples and pumice groundmass glass (yellow circles) plotted in A) a TAS diagram and in B) CaO/Al_2O_3 vs K_2O/Na_2O diagram. Both groundmass glasses and MI from scoriae show a shoshonitic composition. In the CaO/Al_2O_3 vs K_2O plot MIs and glasses cluster in the Stromboli HP field. *LP and HP field of Stromboli MIs and groundmass glasses are represented accordingly to Métrich et al. (2005, 2001) and Pioli et al. (2014). For comparison, we also report the more evolved groundmass glass compositions (gray circles) found by Gurioli et al. (2014).

Figure 7. (A-B) Transmission microscope images of naturally-quenched olivine-hosted melt inclusions; (C-F) back scattered images of significant large-size MIs. MIs are glassy and fully enclosed, without any significant post-entrapment transformation. For each olivine crystal we indicate the forsterite (Fo) content. Cpx: clinopyroxene crystal included in the melt inclusion.

Figure 8. Variation histograms for FeO and K_2O in (A-B) groundmass glasses and (C-D) melt inclusions. Histograms are unimodal and for each oxide we observe a main mode fixed at the same value. This variation is also observed in term of MgO, FeO, Al_2O_3 and K_2O.
