Metabolomic screening of fasting plasma from nondiabetic subjects identified α-hydroxybutyrate (α-HB) and linoleoylglycerophosphocholine (L-GPC) as joint markers of insulin resistance (IR) and glucose intolerance. To test the predictive value of α-HB and L-GPC for incident dysglycemia, α-HB and L-GPC measurements were obtained in two observational cohorts, comprising 1,261 nondiabetic participants from the Relationship between Insulin Sensitivity and Cardiovascular Disease (RISC) study and 2,580 from the Botnia Prospective Study, with 3-year and 9.5-year follow-up data, respectively. In both cohorts, α-HB was a positive correlate and L-GPC a negative correlate of insulin sensitivity, with α-HB reciprocally related to indices of β-cell function derived from the oral glucose tolerance test (OGTT). In follow-up, α-HB was a positive predictor (adjusted odds ratios 1.25 [95% CI 1.00–1.60] and 1.26 [1.07–1.48], respectively, for each standard deviation of predictor), and L-GPC was a negative predictor (0.64 [0.48–0.85] and 0.67 [0.54–0.84]) of dysglycemia (RISC) or type 2 diabetes (Botnia), independent of familial diabetes, sex, age, BMI, and fasting glucose. Corresponding areas under the receiver operating characteristic curve were 0.791 (RISC) and 0.783 (Botnia), similar in accuracy when substituting α-HB and L-GPC for incident dysglycemia, independent of familial diabetes, sex, age, BMI, and fasting glucose. Corresponding areas under the receiver operating characteristic curve were 0.791 (RISC) and 0.783 (Botnia), respectively, for each standard deviation of predictor.

Physiological significance of these findings is that the markers identified—α-HB and L-GPC—may be useful as biomarkers of IR and glucose intolerance.

T

See accompanying commentary, p. 1384.
healthy. Initial exclusion criteria were treated for obesity, hypertension, lipid disorders or diabetes, pregnancy, cardiovascular or chronic lung disease, weight change of ≥5 kg in last 6 months, cancer (in last 5 years), and renal failure. Exclusion criteria after screening were arterial blood pressure ≥140/90 mmHg, fasting blood glucose ≥7.0 mmol/L, 2-h plasma glucose (on a standard, 75-g oral glucose tolerance test [OGTT], performed in each subject) ≥11.0 mmol/L or known diabetes, total serum cholesterol ≥7.8 mmol/L, serum triglycerides ≥1.6 mmol/L, and electrocardiogram abnormalities. Baseline examinations began in June 2002 and were completed in July 2005 and included 1,538 subjects receiving an OGTT. Of these, 1,308 also received a euglycemic hyperinsulinemic clamp and constitute the baseline cohort; cross-sectional data on this cohort have been published (8).

All subjects of the baseline cohort were recalled 3 years later, and 1,048 (80%) participated in the follow-up evaluation (8–10). The baseline anthropometric and metabolic characteristics of the 260 subjects who were lost to follow-up were very similar to those of the subjects who participated (data not shown). The follow-up study included all the baseline anthropometric measurements and the OGTT. Fasting plasma samples were also obtained from 47 T2D patients (14 men, 33 women; age, 56 ± 7 years; BMI, 20.9 ± 4.2 kg/m²; HbA₁c, 7.4 ± 0.8%; fasting glucose, 9.3 ± 1.9 mmol/L) after 4 weeks of oral hypoglycemic agents washout.

The Botnia study is a family-based, observational familial study started in 1990 on the West coast of Finland aiming at identifying diabetes susceptibility genes (11). The Botnia study included 2,054 individuals (1,021 women) and their spouses (1,263 men and 1,507 women; mean age, 45 years), 151 of whom developed T2D during a median 9.5-year follow-up period (7). All subjects were given information about exercise and healthy diet and exposed at 2- to 3-year intervals to a new OGTT. Baseline measurements of α-HB and L-GPC were obtained from 2,580 Botnia participants, with 9.5-year median follow-up data analyzed.

Ethics committee approval was obtained by recruiting centers.

**Measures.** Blood samples were taken before and 30, 60, 90, and 120 min (30, 60, and 120 min in Botnia) after a 75-g OGTT, with a follow-up test repeated in RISC and Botnia. In RISC, clamps and OGTTs were performed in all subjects within same week (10).

**Targeted metabolite analysis.** For absolute quantitation, metabolites were analyzed by an analytically and clinically validated isotope-dilution ultra-high-performance liquid chromatography tandem mass spectrometry (UHPLC-MS/MS) assay developed and conducted in a Clinical Laboratory Improvement Act/College of American Pathologists-accredited laboratory, as a consolidated version of the assay described previously (4). In brief, 50 μL EDTA plasma samples were spiked with internal standards and subsequently subjected to protein precipitation by mixing with 250 μL methanol. After centrifugation, aliquots of clear supernatant were injected into an UHPLC-MS/MS system, consisting of a Thermo TSQ Quantum Ultra Mass Spectrometer and a Waters Acquity UPLC system equipped with a column manager module in 2.5-min assay. α-HB, L-GPC, and oleic acid were eluted with a gradient on Waters Acquity single RPC-18 column (2.1 mm 50 mm, 1.7-mm particle size) at a mobile-phase flow rate of 0.4 mL/min at 40°C. Ionization was achieved by a heated electrospray ionization source. Quantitation was performed based on the relative standard deviation of intra-assay responses (rSDs). Statistical analysis was performed using the R statistical computing software (version 2.13.0). The least-squares regression analysis generated from fortified calibration standards in an artificial matrix, prepared immediately before each run, with coefficients of variation for α-HB, L-GPC, and oleic acid at 4.0, 6.3, and 4.6%, respectively, based on Botnia data (n = 2,585) and 146 replicates over 9 months. Stable deuterium-labeled compounds (α-HB-D₆, L-GPC-D₆, and oleic acid-D₁₈) were used as internal standards.

For targeted quantitation of amino acids, we used the AbsolutIDQ p180 kit (BIOCRAVES Life Sciences AG, Innsbruck, Austria) on an API 4000 LC-ESI-MS/MS System (AB Sciex Deutschland GmbH, Darmstadt, Germany) equipped with an Agilent 1200 Series HPLC and an HTC PAL auto sampler (CTC Analytics, Zwingen, Switzerland). The instrument was controlled by Analyst 1.5.1 software. Samples were handled and preprocessed using a Hamilton Micro Literature (Hamilton Bonaduz AG, Bonaduz, Switzerland) and a nitrogen evaporator (Porvar, Ultravap). For data preprocessing and analysis, we followed the operating procedure of a proprietary method, as described in U.S. patent application (US 2007/0004044). In brief, 10 μL serum were put on the kit 96-well plate loaded with internal standards. After derivatization of the amino acids with phenylisothiocyanate, metabolite extraction with organic extraction solvent, filtration by centrifugation, and dilution with H₂O, the samples were run on the HPLC and MS instruments. Calculation of metabolite concentrations based on internal standards was performed with the MetQ package, which is an integral part of the kit. In addition, the data were corrected for batch effects. The AbsolutIDQ methods were proven to be in conformance with the U.S. Food and Drug Administration Guidance (Guidance for Industry—Bioanalytical Method Validation, May 2001) requiring proof of reproducibility within an given error range (5).

**In vitro studies.** The clonal INS-1e cell line, derived and selected from the parental rat insulinoma, was donated by Dr. Claes Wollheim (University of Geneva, Switzerland). Tissue culture reagents were obtained from Gibco Invitrogen (Bael, Switzerland), α-HB from Sigma-Aldrich (St. Louis, MO), and L-GPC from Avanti Polar (Alabaster, AL). Cell culture and α-HB layer culture in RPMI-1640 medium containing 11.1 mmol/L glucose. The culture medium was supplemented with 10% heat-inactivated FCS, 1 mmol/L sodium pyruvate, 10 mmol/L HEPES, 2 mmol/L glutamine, 50 μmol/L β-mercaptoethanol, 100 units/mL penicillin, and 100 μg/mL streptomycin. Cells were cultured at 37°C in a humidified 95% air, 5% CO₂ atmosphere. Cells were seeded in a density of 1.5 × 10⁴ cells per well at least 96 h prior to each experiment. The response to glucose was tested at passage between 50 and 95. At 48 h before the experiment, when ~80% confluence had been reached, cells were incubated in fresh RPMI-1640 medium containing 11 mmol/L glucose, in the presence or absence of α-HB (at a concentration of 6, 18, or 54 μg/mL) or L-GPC (at a concentration of 5, 15, or 45 μg/mL). Before experiments, cells were maintained for 1 h in glucose-free culture medium. Cells were washed twice and preincubated at 37°C for 1 h in 1 mL glucose-free Krebs-Ringer bicarbonate HEPES buffer (KRHB) containing 135 mmol/L NaCl, 3.6 mmol/L KCl, 5 mmol/L NaHCO₃, 0.5 mmol/L NaH₂PO₄, 0.5 mmol/L MgCl₂, 1.5 mmol/L CaCl₂, 10 mmol/L HEPES, and 0.1% BSA (glucose-free and free fatty acid [FFA]-free), pH 7.4. Cells were washed once with glucose-free KRH-HEPES buffer and subsequently incubated for 60 min with glucose-free PRO-DISCA medium containing 11 mmol/L glucose plus 10 mmol/L-L-arginine. At the end of incubation, supernatants were collected to measure insulin concentration by enzyme-linked immunosorbent assay (Millipore Corporation, Billerica, MA).

**Data analysis.** Fat-free mass (FFM) was measured by electrical bioimpedance (8). Glucose tolerance was categorized as normal glucose tolerance (NGT; fasting glucose <6.1 mmol/L and 2-h glucose <7.8 mmol/L), impaired glucose tolerance (IGT; fasting glucose <7.0 mmol/L and 2-h glucose >7.8 and <11.1 mmol/L), and T2D (fasting glucose ≥7.0 mmol/L or 2-h glucose ≥11.1 mmol/L, or antidiabetic treatment). Impaired fasting glycaemia (IFG) was defined as fasting glucose ≤7.0 and ≥6.1 mmol/L and 2-h glucose <7.8. IFG and IGT were pooled as impaired glucose regulation (IGR).

On the basis of observed OGTT changes at follow-up, RISC participants were classified as stable NGT (i.e., NGT at baseline and follow-up) and progressors (i.e., NGT to IFG → IGT, IFG to IGT → IFG, IGT to T2D, IFG to IGT → T2D, or IGT to T2D between baseline and follow-up).

Insulin sensitivity was the M value during final 40 min of clamp normalized to FFM (μmol · min⁻¹ · kg⁻¹FFM). In Botnia, insulin sensitivity was estimated (εM) from plasma glucose and insulin concentrations measured during OGTT according to Stumvoll et al. (12).

**β-Cell function.** In RISC, β-cell function was expressed as β-cell glucose sensitivity (β-GS) as derived from mathematical modeling of plasma glucose and C-peptide response to glucose ingestion (13) with use of C-peptide deconvolution analysis from Van Cauter et al. (14). β-GS is the dose–response function relating insulin secretion rates to plasma glucose concentrations during dynamic testing. In Botnia, C-peptide measurements were not available. Therefore, the ratio of the insulin-to-glucose (I:G) area under the curve (AUC) was used as a surrogate index of β-cell function.

**Statistical analysis.** Data are presented as mean ± SD or, for variables with a skewed distribution, as median (interquartile range). Group values were compared by Mann-Whitney (or Kruskal-Wallis) test for continuous variables or χ² for nominal variables, and paired group values were compared by Wilcoxon signed-rank test. Simple associations were tested by Spearman correlation coefficient (r). General linear models were used to test for associations while controlling for potential confounders (center, sex, age, BMI), and strength of adjusted associations was expressed as partial correlation coefficients (r). Logistic regression was used to predict progression; odds ratios and 95% CIs were expressed for one SD change in each explanatory variable. Performance of different logistic models was assessed as the C statistic (area under receiver operating characteristic [ROC] curve). For in vitro data, two-way ANOVA was used to simultaneously test for effect on insulin release and the effect of α-HB or L-GPC concentrations. Statistical analyses were run using JMP 7.0 software (SAS Institute, 2007). A two-sided P < 0.05 was considered significant.

**RESULTS.** Baseline. Data of RISC participants are given in Table 1 in 1,115 NGT subjects by quartile of insulin sensitivity (M value from clamp), IGR, and T2D subjects. Familial diabetes, age, BMI, 2-h glucose, fasting insulin, and fasting FFA concentrations were progressively higher along M quartiles in NGT, IGR, and T2D subjects, whereas β-GS was progressively lower. Across these groups, fasting...
levels of α-HB were progressively higher, whereas L-GPC concentrations showed an inverse gradient, with respective highest and lowest levels observed in T2D.

After adjusting for sex, age, BMI, and study site, α-HB and L-GPC concentrations were directly and inversely associated with insulin sensitivity (M), respectively (adjusted \( r^2 = 0.33 \) and 0.34, respectively, both \( P < 0.0001 \); Supplementary Fig. 1). In the same model, α-HB was reciprocally related to β-cell function (β-GS, partial \( r = -0.11, P = 0.0002 \)), whereas L-GPC was unrelated. By defining IR as an M value in the bottom quartile of NGT subjects (<39 \( \mu \text{mol} \cdot \text{min}^{-1} \cdot \text{kg}_{\text{FFM}}^{-1} \)), α-HB concentration in the top quartile of its own distribution (>548 \( \mu \text{g/mL} \)) confers an IR risk of 2.84 (95% CI 2.04–3.95), whereas an L-GPC concentration in the bottom quartile of its distribution (<11.78 \( \mu \text{g/mL} \)) confers a risk of 3.14 (2.60–4.52). In the 122 NGT subjects falling in the highest α-HB quartile and the lowest L-GPC quartile, the risk of IR is 4.14 (2.60–6.70). Prediction of IR (defined as above) increases from a ROC of 0.801 for the difference between IGR and NGT by Mann-Whitney test. 

Data of Botnia participants are given in Table 2 by quartile of eM (Stumvoll index) for the 1,811 NGT subjects and separately for 642 IGR subjects. By study design, prevalence of familial diabetes was high in this cohort and similar across eM quartiles in NGT. Age, BMI, fasting and 2-h glucose concentrations, and fasting insulin concentrations were progressively higher across eM quartiles and IGR, whereas β-cell function (as measured by I-to-G ratio) was highest in the most IR quartile and lower in IGR subjects, indicating incipient β-cell failure. α-HB levels were progressively higher across these groups, whereas L-GPC concentrations showed an inverse gradient. In the whole cohort, eM was negatively associated with α-HB and positively related to L-GPC (partial \( r = -0.19 \) and 0.22, respectively, both \( P < 0.0001 \)) after adjusting for familial diabetes, sex, age, and BMI. In the same adjusted model, the I-to-G ratio was reciprocally related to α-HB (partial \( r = -0.09, P < 0.0001 \)), whereas L-GPC was unrelated.

Follow-up. In RISC (Table 3), GT was still normal in 779 subjects (stable NGT) and had deteriorated in 123 (progressors). The baseline clinical phenotype of progressors included more familial diabetes, higher age, BMI, fasting

The predictivity of α-HB and L-GPC for incident dysglycemia (RISC) or T2D (Botnia) was evaluated in multivariable models including classical predictors. We found generally similar odds ratios between the two populations. BMI and fasting glucose were positive predictors in both cohorts, whereas familial diabetes and age were stronger positive predictors in Botnia than RISC. In both cohorts, baseline α-HB was a positive predictor and L-GPC a negative predictor of almost superimposable strength (Fig. 1).

We next compared the ability of α-HB and L-GPC to predict dysglycemia/T2D with that of traditional clinical models. As detailed in Table 5, adding fasting plasma glucose to the standard clinical predictors (familial diabetes, sex, age, and BMI) increased the ROC area under the curve by 0.044 in RISC and 0.017 in Botnia. Upon adding also the 2-h postglucose plasma glucose concentration, ROC area rose by a further 0.024 in RISC and 0.022 in Botnia. By replacing 2-h glucose with α-HB and L-GPC, very similar ROCs were observed in RISC (0.790) and Botnia (0.783). Finally, adding α-HB and L-GPC to both fasting and 2-h glucose improved the ROC by 0.018 in RISC and by 0.008 in Botnia. Thus the two biomarkers matched the predictivity of an OGTT (fasting insulin making a negligible contribution) in both cohorts. Interestingly, including the actual measurements of insulin sensitivity and β-cell function in the 2-h glucose model yielded ROC values of 0.817 and 0.794 in RISC and Botnia, respectively (i.e., only 0.016 and 0.011 higher than the fasting biomarkers model).

**In vitro studies.** Because levels of α-HB and L-GPC were predictive of dysglycemia, we also tested their activity on insulin secretion in INS-1E cells. Insulin release increased as glucose concentrations rose from 3.3 to 20.0 mmol/L and was potentiated by adding arginine to 20.0 mmol/L glucose. Overall, preincubation with α-HB inhibited, and preincubation with L-GPC potentiated, glucose- and glucose/arginine-induced insulin release in a dose-dependent manner (Supplementary Fig. 2). More specifically, the effects of α-HB and L-GPC both appeared to be exerted on insulin secretion at low glucose concentrations. For example, L-GPC dose-dependently increased insulin release at 3.3 mmol/L glucose (from 42 ± 6 to 73 ± 13 nmol/mL at the highest L-GPC dose, P < 0.01), and α-HB tended to dose-dependently decrease insulin release at 3 mmol/L glucose.

**Amino acid profile.** To further examine these biomarkers in the context of other metabolic pathways in vivo, we measured amino acids and fatty acids in 542 representative subjects from Botnia (Supplementary Table 1), with progressors and nonprogressors having a similar clinical phenotype as the entire cohort (compared with Table 2). Notably, branched-chain amino acids (BCAAs; leucine, isoleucine, valine) and three major glucogenic amino acids (alanine, glutamate, arginine) were increased, whereas glycine was significantly decreased, in progressors versus nonprogressors. Increased concentrations of BCAAs and fatty acids, such as oleate, were positively related to α-HB, whereas L-GPC and insulin sensitivity were reciprocally related to α-HB (Fig. 2). In addition, oleate and L-GPC were reciprocally related to one another (with partial r of −0.23, P < 0.0001 after adjusting for sex, age, BMI; Supplementary Fig. 3).

**DISCUSSION**

With T2D prevalence continuing to increase worldwide, there is interest in identifying high-risk patients with more
sensitivity than currently feasible. Because IR is a risk factor for IGT and T2D (15), we tested whether newly identified markers of insulin sensitivity and β-cell function (6) could predict deterioration of glucose tolerance. We found α-HB and L-GPC were related to IR in an opposite manner—the former positive, the latter negative—in the RISC and Botnia cohorts, independently of known determinants of insulin sensitivity and of one another. Fasting concentrations of α-HB and L-GPC measured at baseline predicted worsening GT independently of classical predictors and with similar power as the 2-h plasma glucose level. Furthermore, changes in α-HB and L-GPC over time tracked with their ability to predict development of dysglycemia in the RISC cohort: at follow-up, α-HB had risen and L-GPC had fallen in subjects who progressed to dysglycemia compared with stable NGT subjects.

Strikingly, odds ratios for both metabolites for risk of progression to dysglycemia were virtually the same in RISC and Botnia (Fig. 1) despite differences in population characteristics, sample size, and end point. Accordingly, the metabolites added 0.028 and 0.017 units of ROC area to the standard model for predicting dysglycemia in RISC and Botnia, respectively. In contrast, fasting insulin, which has been shown to predict T2D in several studies (16–18), did not contribute to predictivity above the joint weight of α-HB and L-GPC in either study. Taken together, these results qualify these metabolites as disease biomarkers through their relation to underlying pathophysiological mechanisms. However, their actual value in routine clinical use requires additional studies, particularly intervention studies.

Because in RISC and Botnia an independent, inverse relationship also existed between α-HB levels and indices of β-cell function (19), we tested the direct impact of these metabolites on insulin secretion. In β-cell in vitro studies, α-HB dose-dependently inhibited overall glucose- and arginine-mediated insulin release. Although this effect must be confirmed in human islets and its mechanisms remain to be investigated, α-HB may mark IR and also β-cell function under diverse circumstances. This use would have utility for clinicians who have available surrogate indices of IR (e.g., homeostasis model assessment-IR [20] or Matsuda index [21]) but must choose among clinical tests of β-cell function (e.g., hyperglycemic clamp, acute insulin response to intravenous glucose, insulinogenic index) that are cumbersome and relatively incongruous with one another (22–24). In this regard, it is notable that L-GPC appeared to exert the opposite effect.

to α-HB on in vitro insulin release, thereby adding to the evidence that certain lipid-signaling molecules (including lysophospholipids) can stimulate glucose-dependent insulin release (25) through lysophospholipid receptors such as G-protein–coupled receptor 119 (26), which localized to pancreatic β-cells. Interestingly, a similar lipid-signaling pathway has been described for G-protein–coupled receptor 119, with its lipid agonist activation playing a role in glucagon-like peptide-1 release in intestinal L-cells (27). Moreover, lysophospholipids have been implicated in other signaling functions related to metabolism, including glucose uptake by adipocytes and myotubes (28,29). Declining L-GPC levels across IR, IGR, and T2D (Table 1 and Table 2) are likely a reflection of an important role for this metabolite in glucose metabolism.

Previous evidence has linked raised concentrations of selected amino acids with obesity and T2D (reviewed in 30). Newgard et al. (1) described a metabolic signature related to BCAAs in obese humans. Fiehn et al. (31) reported increased concentrations of leucine and valine—in addition to lipid substrates—in a small group of obese T2D women. Lower glycine concentrations have been reported in IR offspring of T2D patients (32), consistent with our observation of lower glycine associated with IR (6). However, compared with such reported analytes, α-HB and L-GPC were more sensitive markers of IR, e.g., able to discriminate insulin sensitive from IR individuals in both NGT and IGR ranges (6).

The pattern of metabolite changes we observed in the Botnia subgroup (Supplemental Table 1) can be organized into a coherent pathway (Supplementary Fig. 3) by assuming IR as a primary determinant of these changes. In this scenario, adipose tissue IR leads to elevated FFA concentrations (33,34), which feed into the TCA cycle and are oxidized at an increased rate, thereby producing an excess of reducing equivalents (NADH). Raised circulating FFA also reconstitutes phospholipids from circulating lipids such as L-GPC. Such overload of the TCA cycle leads to accumulation of amino acids such as glutamate and alanine, as well as α-ketobutyrate (6), substrate precursor of α-HB via propionyl-CoA. Oxidative stress and IR raise demand for glutathione synthesis (35), of which α-ketobutyrate and α-HB are by-products, and depletes glutathione constituents like glycine, whose levels are decreased in association with IR and T2D progression (Supplementary Table 1). Furthermore, by reducing amino acid transport (36) and clearance (31,37), IR also raises BCAAs (6,30,38–40), which also feed into the TCA cycle, directly (leucine) or via propionyl-CoA. Thus, increased α-HB and decreased L-GPC levels serve as readouts of metabolic overload (elevated NADH-to-NAD⁺ ratio) and reduced glucose metabolism in both IR and the earliest phases of dysglycemia (6,41) (Fig. 3). Finally, the abnormal α-HB and L-GPC levels and their biological activity on in vitro glucose-stimulated insulin release may translate into a burden on in vivo β-cell function.

K.-P.A., M.V.M., and W.E.G. are employees of Metabolon, Inc. No other potential conflicts of interest relevant to this article were reported.

E.F. contributed to study concept and design, to acquisition, analysis, and interpretation of data, to statistical analysis (RISC and Botnia), and to study supervision (RISC). A.N. and A.M. contributed to analysis and interpretation of data. S.C., M.N., K.-P.A., M.V.M., G.K., J.A., and T.T. contributed to acquisition of data. V.L. contributed to study concept and design, to acquisition of data, and to statistical analysis (Botnia). L.G. contributed to study concept and design and to acquisition, analysis, and interpretation of data. E.F. is the guarantor of this work.

**FIG. 2.** Relationship between L-GPC, α-HB, BCAA, and oleate levels and insulin sensitivity. Fasting plasma concentrations of the BCAAs (sum of leucine, isoleucine, and valine) by quartile of α-HB concentrations in 542 subjects from the Botnia study are shown. Also plotted are plasma L-GPC and oleate concentrations, and eM values by quartile of α-HB. Plots are mean ± SEM. Note that the horizontal scale for oleate and L-GPC has been shifted to avoid overlapping symbols.
and, as such, had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Parts of this study were presented as an abstract in the poster session at the 72nd Scientific Sessions of the American Diabetes Association, Philadelphia, Pennsylvania, 8–12 June 2012.

The authors thank Kay Lawton and Eric Button of Metabolon, Inc., for their helpful comments in preparation of the manuscript.
